FIG. 8.—Phenoxybenzamine (PBZ) and chlorpromazine (CPZ) both improved organ survival significantly ($P < 0{\cdot}001$) when each was added to the preservation solution. Storage for 14 hours at 5° C.

At this stage in the study, therefore, a solution had been devised which would successfully preserve the rat heart for up to 14 hours. This solution contained a balanced salt content, buffered with Tris-HCl at pH 7·5 at 5° C., 1 g. glucose per litre, and 5 per cent Dextran 40.

Effect of Various Additives on Organ Preservation.—

1. *Phenoxybenzamine and Chlorpromazine.*—These compounds have been used in various preservation solutions because of their effect on the stabilization of lysosomes; they also may improve flow through the organ (Belzer, Reed, Pryor, Kountz, and Dunphy, 1970; Collins and others, 1969a, b; Fonkalsrud, Rangel, Byfield, Bruckner, Stevens, and Dinbar, 1969; Rangel, Bruckner, Byfield, Adomian, Dinbar, and Fonkalsrud, 1970). In the present experiments phenoxybenzamine was used at a concentration of

25 mg. per litre and chlorpromazine at 100 mg. per litre. The results are shown in *Fig.* 8. Both compounds significantly increase survival over that of the controls ($P < 0{\cdot}001$). There is thus good evidence that these compounds should be used in organ-storage solutions. One disquieting feature, however, is the recent report that phenoxybenzamine in dilute physiological solution may decompose rapidly (Bird, 1970).

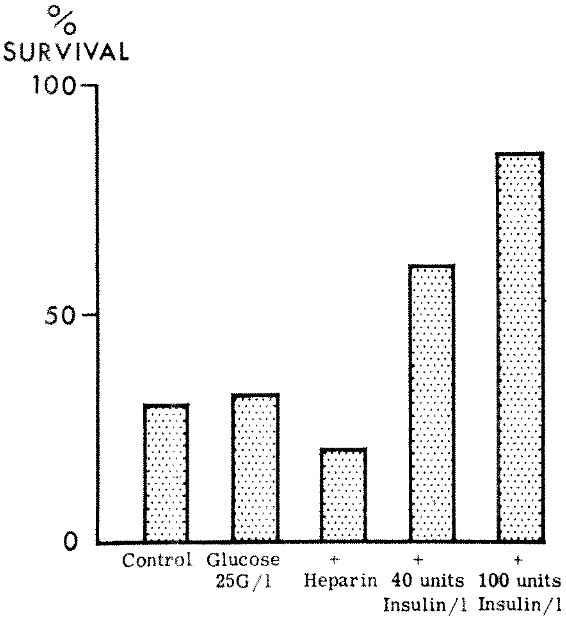

FIG. 9.—The addition of insulin (40 U. per litre) to the solution significantly increased organ survival ($P < 0{\cdot}01$). Preservation was further improved when the concentration of insulin was increased to 100 U. per litre ($P < 0{\cdot}001$). The addition of heparin or increasing the glucose concentration did not significantly increase survival. Storage for 14 hours at 5° C.

Table I.—COMPOSITION OF STANDARD SOLUTION

Sodium	140 mEq./l.
Potassium	13·0 mEq./l.
Calcium	1·6 mEq./l.
Magnesium	2·1 mEq./l.
Chloride	145 mEq./l.
Phosphate	10·0 mEq./l.
Glucose	1 g./l.
Insulin	100 U./l.

5 per cent Dextran 40
0·01 M Tris buffer, *p*H 7·5, at 5° C.
2 ml./g. of tissue infused
Storage temperature: 5° C.

2. *Effect of Heparin, Glucose, and Insulin.*—The addition of heparin (10,000 U. per litre), glucose (25 g. per litre instead of the 1 g. per litre used in the control solution), and insulin (40 and 100 U. per litre) was assessed in the rat heart model. Whereas the use of the increased glucose concentration or of heparin did not increase organ survival, the addition of either 40 or 100 U. of insulin per litre did significantly increase the survival ($P < 0{\cdot}01$ and $P < 0{\cdot}001$). The results are shown in *Fig.* 9.

3. *Combinations of Additives.*—The three compounds, phenoxybenzamine, chlorpromazine, and insulin, have been used in combination. There was no significant increase in survival over the results with each compound used alone. The only significant feature was that when phenoxybenzamine and chlorpromazine are used together there is a definite decrease in survival ($P < 0{\cdot}02$). On this evidence, therefore, there is no justification for using more than one of these compounds in a preservation solution.

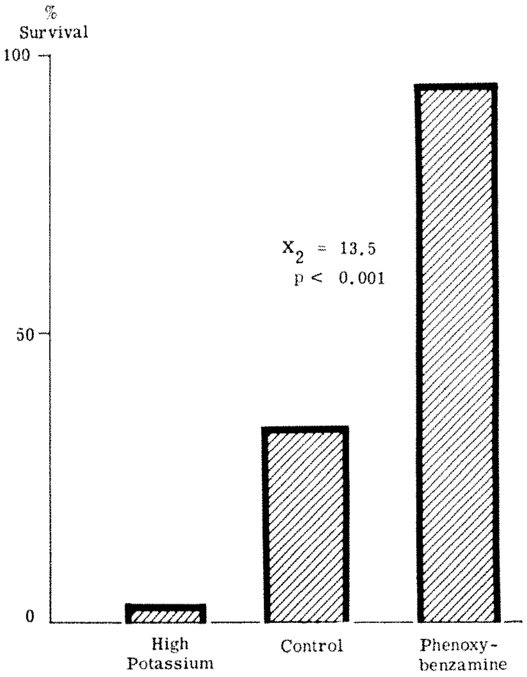

FIG. 10.—A potassium concentration of 115 mEq./l. significantly decreased organ survival ($P < 0{\cdot}01$), whereas phenoxybenzamine added to the control solution improved survival ($P < 0{\cdot}001$). Storage for 14 hours at 5° C.

At this point a standard solution was devised, the composition of which is shown in *Table I*. Insulin, at 100 U. per litre, was chosen rather than phenoxybenzamine or chlorpromazine because of its greater stability in solution. This solution will be referred to as the standard solution in subsequent experiments.

Comparison with Collins's and Gelin Techniques.—

1. *Comparison with Collins's C4 Solution.*—The standard solution was significantly better than the Collins's solution ($P < 0{\cdot}01$) for 16 hours' storage at 5° C. To find out why this was so the standard solution was modified to contain either a high potassium concentration (115 mEq./l.) or phenoxybenzamine. The results with phenoxybenzamine have already been described. When a high potassium concentration was used the results were significantly worse ($P < 0{\cdot}01$) (*Fig.* 10). Thus, the poor results with the Collins's solution may be related to the high potassium value. It is of interest that in a recent publication Collins, Hartley, and Clunie (1972) suggest that this concentration of potassium may in fact be too high. This has also been pointed out by other workers (Abouna, 1968; Calman and Bell, 1971).

2. *Comparison with the Gelin Technique.*—When the standard solution was compared with the Gelin

echnique (*Fig.* 11) it was found to be an inferior organ-preservation solution ($P < 0{\cdot}01$). This was at first surprising since the *p*H values of the three basic solutions of the Gelin technique are outside the physiological range, being *p*H 6, 6, and 8 respectively. An analysis was then made of the component parts of the Gelin technique by assessing each part separately in ombination with the standard solution. The results are shown in *Fig.* 12. When the lignocaine flush (0·5 per cent w./v.) was used before the standard solution or when lignocaine (2 per cent w./v.) was added to the standard solution there was a significant increase in survival ($P < 0{\cdot}05$). On the other hand, if fructose/bicarbonate (10 per cent fructose/1·4 per cent bicarbonate in equal volumes) was used there was a significant decrease in survival ($P < 0{\cdot}01$).

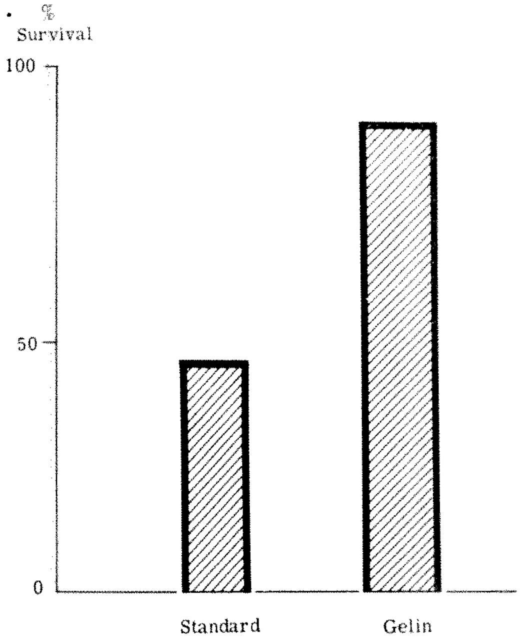

Fig. 11.—The Gelin technique was found to be significantly better ($P < 0{\cdot}01$) than the standard solution. Storage for 16 hours at 5° C.

Table II.—Composition of Modified Standard Solution

Solution 1

Sodium	140 mEq./l.
Potassium	13·0 mEq./l.
Calcium	1·6 mEq./l.
Magnesium	1·6 mEq./l.
Chloride	145 mEq./l.
Phosphate	10 mEq./l.
Glucose	1 g.

0·01 M Tris buffer, *p*H 7·5, at 5° C.
0·5 ml./g. of tissue infused

This is made up to 750 ml. and 60-ml. aliquots are taken. To these aliquots 20 ml. of 2 per cent lignocaine are added, giving a final concentration of 0·5 per cent lignocaine; 5000 U. of heparin are then added

Solution 2

As in standard solution (*Table I*).
25 ml. of 2 per cent lignocaine are added per litre.
1·5 ml./g. of tissue infused

With this information a modified standard solution was then devised (*Table II*) based on the standard solution, incorporating the 0·5 per cent lignocaine flush in a buffered solution and 2 per cent lignocaine, but without the fructose/bicarbonate. The results show that this solution (*Fig.* 13) is significantly better ($P < 0{\cdot}05$) than the Gelin technique. It is important to note that the storage time has been prolonged over the previous experiment and this accounts for the

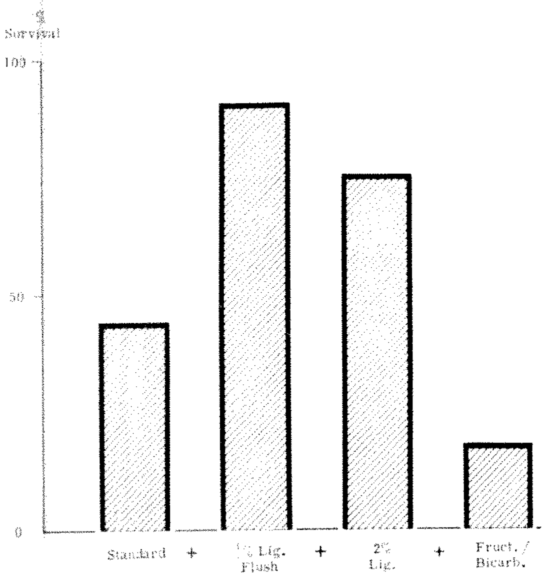

Fig. 12.—Fructose/bicarbonate added to the standard solution decreased organ survival. In contrast, a 0·5 per cent lignocaine flush prior to infusion or the incorporation of lignocaine (2 per cent) in the solution significantly enhanced survival ($P < 0{\cdot}05$). Storage for 16 hours at 5° C.

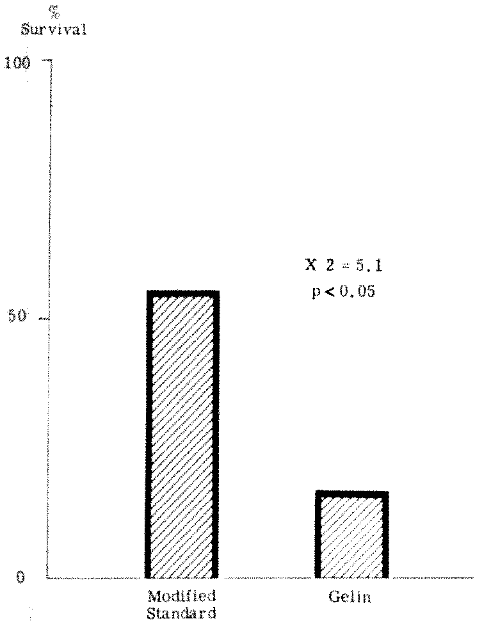

Fig. 13.—The modified standard solution (infusion preceded by 0·5 per cent lignocaine flush with 2 per cent lignocaine in the preservation solution) was superior to the Gelin technique ($P < 0{\cdot}05$) with 17 hours' storage at 5° C.

difference in survival rate from the previous results (*Fig.* 11).

3. *Effect of High Concentrations of Magnesium.*—Several workers have suggested that a high magnesium concentration is important, both in the dog kidney (Collins and others, 1972) and the rat heart (Kamiyama, Webb, and Ecker, 1970). To assess this the second part of the modified standard solution was altered to contain 60 mEq. magnesium sulphate per litre with a corresponding reduction in the sodium concentration (*Table III*). When this solution was compared with the modified standard solution it was found to be significantly better ($P < 0{\cdot}05$).

Table III.—COMPOSITION OF HIGH-MAGNESIUM SOLUTION

Solution 1

As in *Table II.*
0·5 ml. per g. of tissue infused

Solution 2

Sodium	70 mEq./l.
Potassium	13·0 mEq./l.
Calcium	1·6 mEq./l.
Magnesium*	60 mEq./l.
Chloride	70 mEq./l.
Phosphate	10 mEq./l.
Glucose	1 g./l.
Insulin	100 U./l.

5 per cent Dextran 40
0·01 M Tris buffer, *p*H 7·5, at 5° C.
2 per cent lignocaine: 25 ml./l.

* As magnesium sulphate.
1·5 ml./g. infused.

CONCLUSIONS

The rat heart is a convenient model for the study of organ preservation. The physiology and biochemistry of this organ have been extensively investigated and the electrocardiographic patterns in various disease states elucidated (Schever and Stezoski, 1968; Cooper, 1969). The rat heart has also previously been used in organ-preservation investigations and the effects of both freezing and various perfusates studied (Karow, Webb, and Stapp, 1965; Webb, Dodds, Unal, Karow, Cook, and Daniel, 1966; Ancona, Frasson, Perracchia, Tonini, and Tremolada, 1970). The method used here is unique in that the viability is assessed after biological perfusion. This has theoretical advantages in that the donor heart is perfused with blood at the correct temperature and oxygen content and with pulsatile flow. In addition, the technique is simple, rapid, and allows statistical evaluation of the results. Viability after storage has been confirmed in this investigation by heterotopic transplantation of the rat heart using the method of Ono and Lindsay (1969). Prolonged survival of these preserved transplants in inbred strains of Wistar rats confirms that our criteria for viability are acceptable.

In this paper the isolated, biologically perfused ra heart has been used to assess a number of aspects o organ preservation. The aim of the present study wa to analyse the constituents of various preservatio media and to develop the most suitable preservatio solution for organ storage. Such a technique has bee developed using a 0·5 per cent lignocaine flus followed by a Dextran-40-based, high-magnesiu solution containing lignocaine and insulin. Sub sequently this solution will be tested with the do kidney, an essential step for validation of the mode prior to its use in humans.

THE EFFECT OF ISCHAEMIC INJURY ON KIDNEYS PRESERVED FOR 24 HOURS BEFORE TRANSPLANTATION

By R. W. G. JOHNSON

DEPARTMENT OF SURGERY, UNIVERSITY OF NEWCASTLE UPON TYNE

SUMMARY

Kidneys have been preserved for 24 hours by three methods—continuous hypothermic perfusion with plasma protein fraction (P.P.F.), simple ice storage using the method of Collins, Bravo-Shugarman, and Terasaki (1969), and a combination of simple ice storage followed by continuous perfusion. Prior to preservation the kidneys were subjected to warm ischaemic intervals varying from 0 to 180 minutes.

Kidneys preserved without warm ischaemia functioned immediately whichever method was used. Kidneys preserved by perfusion after up to 60 minutes of warm ischaemia returned to normal function; kidneys preserved by Collins's method did not function after ischaemic injury.

The period of storage of ischaemically injured kidneys initially preserved by Collins's method can be extended to 24 hours by subsequent continuous perfusion, but the results are not as good as with perfusion alone. A fall in perfusate pH was a reliable indication that kidneys would not function after 24 hours' storage.

SUCCESS in transplanting human cadaver kidneys depends on good tissue typing and on the ability to distribute the kidneys to the best-matched recipients. These two factors lose their value if the kidney cannot be sufficiently well preserved to ensure immediate function, since even short periods of impaired renal function may mask early rejection which may then progress unrecognized to beyond control.

Twenty-four-hour renal preservation with immediate return of function has often been achieved in the laboratory (Belzer, Ashby, and Dunphy, 1967; Collins, Bravo-Shugarman, and Terasaki, 1969; Scott, Morley, and Swinney, 1969). These laboratory results are not easily applied to the clinical situation because human cadaver kidneys have been exposed to injury whereas the kidneys of laboratory animals are fresh.

Warm ischaemia is an important cause of injury, the severity of which increases with the duration of ischaemia. The warm ischaemic interval is defined as that period between circulatory arrest and effective cooling of the donor organ. In human cadaveric renal transplantation such an interval is unavoidable.

The duration of warm ischaemia compatible with 24-hour preservation is not known; neither is it known which of the methods available best preserves ischaemically injured kidneys.

The aim of the present work was to investigate the effect of warm ischaemic injury on kidneys preserved for 24 hours either by simple ice storage (Collins and others, 1969) or by continuous perfusion with oxygenated plasma-protein fraction (Johnson, Anderson, Flear, Murray, Swinney, and Taylor, 1971).

Since facilities for continuous perfusion are not generally available in this country the practicability of combining short periods of ice storage followed by 24-hour perfusion has also been studied.

During perfusion the physical and biochemical characteristics of the kidney were recorded in an attempt to predict subsequent function after reimplantation.

MATERIALS AND METHODS

Adult trail hounds, weighing between 15 and 30 kg., were used. Each dog was anaesthetized with Nembutal, the trachea was intubated, and anaesthesia maintained with nitrous oxide and oxygen.

Table I.—C4 SOLUTION (COLLINS AND OTHERS, 1969)

KH_2PO_4	2·05 g./l.
$K_2HPO_4.3H_2O$	9·70 g./l.
KCl	1·20 g./l.
$NaHCO_3$	0·84 g./l.
$MgSO_4.7H_2O$	7·38 g./l.
Procaine HCl	0·10 g./l.
Heparin	5000 I.U./l.
Phenoxybenzamine	0·025 g./l.
Glucose	25 g./l.
pH	7·0 at 25° C.

Phenoxybenzamine was added immediately before use; when the cloudiness disappeared glucose and magnesium sulphate were added as 50 per cent solutions. C4 was used only if the solution was clear and free from crystals.

Nephrectomy.—The right kidney was exposed through a loin incision. The kidney was handled as little as possible; the renal artery and vein were clamped close to their origins and divided. Kidneys being exposed to a warm ischaemic interval were then allowed to remain undisturbed in the peritoneum for periods up to 180 minutes.

Initial Cooling.—After removal, the kidneys were immersed in iced saline slush, the artery and vein were cannulated, and the kidneys were washed through with cold solution by gravity infusion from 150 cm. During this initial wash-out rate of flow was measured by collecting consecutive minute samples of the venous effluent in separate pots.

Wash-out Solutions.—

1. C4 *Solution.*—This solution was made up as described by Collins and others (1969); its final composition is shown in *Table I.* The Collins's method of ice storage simply comprised washing the kidneys out with cold C4 solution which approximates in composition to intracellular fluid and then placing them in a bag containing C4 solution in a refrigerator at 4° C.

2. *Saline Wash-out.*—Kidneys being prepared for continuous perfusion were washed out with sodium chloride (0·94 per cent w./v.) containing phenoxybenzamine (2·5 mg. per cent w./v.) and procaine hydrochloride (2·5 mg. per cent w./v.).

After wash-out the venous cannula was removed.

Perfusion Apparatus.—(This apparatus was designed and built in the Department of Surgery, University of Newcastle upon Tyne, by Mr. D. F. Scott and Mr. W. G. Leslie.) The apparatus comprises a Perspex kidney box, a disk oxygenator, a Watson-Marlow roller pump, and a Churchill heat-exchange unit (*Fig.* 1). The perfusion fluid recirculates through polyvinylchloride tubing. A manometer, a bubble trap, and a filter are included in the circuit.

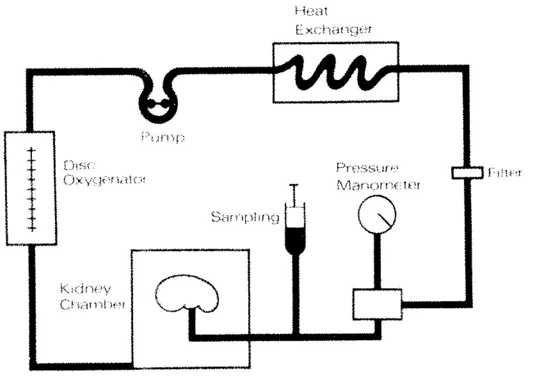

FIG. 1.—The perfusion circuit designed and built by Mr. W. G. Leslie and Mr. D. F. Scott in the Department of Surgery, University of Newcastle upon Tyne.

Table II.—ADJUSTMENTS TO PLASMA-PROTEIN FRACTION

P.P.F.$_{(1)}$ (Normal $[K]^+$)		P.P.F.$_{(2)}$ (High $[K]^+$)	
$NaHCO_3$	4 mEq./l.	H_2O	1 : 4

Ca^{++}	4·4 mg. per cent	4·4 mg. per cent
Cl^-	100–110 mEq./l.	100–110 mEq./l.
HCO_3^-	20–25 mEq./l.	25–30 mEq./l.
Total protein	4·3–4·5 g. per cent	3·4–4·0 g. per cent
Albumin	4·3–4·5 g. per cent	3·4–4·0 g. per cent
Glucose	130 mg. per cent	150 mg. per cent
Fat	15–20 mg. per cent	10–15 mg. per cent
Osmolality	300 m.osmol./l.	275 m.osmol./l.

Perfusion Solution.—Plasma-protein fraction (P.P.F.) was used. Its composition was modified in two ways to make two solutions: P.P.F.$_{(1)}$ which resembles serum, and P.P.F.$_{(2)}$ which has an increased potassium concentration in an attempt to minimize the cellular leakage of this electrolyte which has been shown to occur at low temperatures (Keeler, Swinney, Taylor, and Uldall, 1966). An evaluation of P.P.F. as a perfusion solution has previously been published (Johnson, Anderson, Flear, Murray, Swinney, and Taylor, 1972). The preparation and final compositions of P.P.F.$_{(1)}$ and P.P.F.$_{(2)}$ are shown in *Tables II* and *III*.

During perfusion the oxygen tension was maintained between 200 and 400 mm. Hg by using 95 per cent oxygen and 5 per cent carbon dioxide. The flow rate was maintained at 1 ml. per g. of kidney per minute. Flow was only adjusted if a systolic pressure of 40 mm. Hg could not be sustained.

The temperature of the perfusion fluid was adjuste to give a renal core temperature of 6° C.

Measurements.—

Perfusion pressure was continuously recorded on Recklar D.B.G.M. air displacement manometer.

*Oxygen tension and p*H were measured on fres samples using an Astrup Blood Micro System B.M.S. (Radiometer, Copenhagen); *p*H values were correcte to 37° C. Lactic dehydrogenase (L.D.H.) wa measured by using a Boehringer T.LAC Biochemic test kit combination.

Renal core temperature was measured with a needl probe, Nihon Kohden MGA III 219.

Reimplantation.—After 24-hour storage th kidney was reimplanted in the dog's pelvis as an auto graft. The renal vein was anastomosed end to side t the common iliac vein and the renal artery wa anastomosed end to end to the external iliac artery The ureter was reimplanted into the base of th bladder through a short submucous tunnel.

Contralateral nephrectomy was performed eithe immediately or on the nineteenth day.

Following contralateral nephrectomy, daily measurements of plasma creatinine and plasma urea were mad until they returned to normal or until the dog die All surviving dogs were killed at 3 months.

RESULTS

Group 1: Kidneys preserved for 24 Hour *without* Warm Ischaemia.—

a. Simple Ice Storage (Collins's Method), wit Immediate Contralateral Nephrectomy.—Five kidney were preserved in this manner; warm ischaemic inter vals were very short, not exceeding 3 minutes. Eac kidney became pink on reimplantation and all 5 mad urine immediately. Following immediate contralater nephrectomy, all 5 kidneys rapidly assumed norm function (*Fig.* 2 A). The highest plasma creatinine wa 3 mg. per cent, and in each instance the plasma creatinine level was less than 2 mg. per cent by th third postoperative day.

Table IV.—RESULTS OF 24-HOUR PRESERVATION B COLLINS'S TECHNIQUE FROM THE DAY AFTER CONTRA LATERAL NEPHRECTOMY

WARM ISCHAEMIA TIME	NO. OF DOGS	NO. OF SURVIVORS	PERCENTAGE SURVIVING	MEAN NO. OF DAYS TO REACH BIO-CHEMICAL NORMALIT	
				Creatinine	Urea
Zero	5	5	100	5	8
30 minutes	8	2	25	28	—
40 minutes	2	0	0	—	—

b. Continuous Perfusion with P.P.F. at 6° C., wit Immediate Contralateral Nephrectomy.—Five kidney were preserved by this method; again contralater nephrectomy was immediate. All 5 kidneys becam pink and made urine at reimplantation. Four kidney rapidly assumed normal function (*Fig.* 2 B). Th highest post-reimplantation plasma-creatinine lev was 2·8 mg. per cent. The remaining dog was foun to have a completely obstructed ureter; this wa treated by reimplantation on the third postoperativ day; subsequent return to normal function wa rapid.

Group II: Kidneys preserved for 24 Hours after 30 to 40 Minutes of Warm Ischaemia.—

a. Simple Ice Storage (Collins's Method), with Delayed Contralateral Nephrectomy (Table IV).—Ten kidneys had 30–40 minutes of warm ischaemia; only 2 functioned sufficiently to sustain life even after contralateral nephrectomy had been delayed until the nineteenth postoperative day. The kidneys generally had a bluish hue when the circulation was opened and though they all eventually became pink only 1 made urine during reimplantation.

Neither of the 2 kidneys which functioned after warm ischaemia returned completely to normal function although 1 of the dogs had a plasma creatinine of less than 2 mg. per cent after 30 days (*Fig.* 3).

In each of the 8 failures the dog was moribund within 5 days of delayed contralateral nephrectomy. Histology of the 2 survivors showed numerous areas of cortical fibrosis with hypertrophy of the residual tubules. The 8 failures all had cortical necrosis.

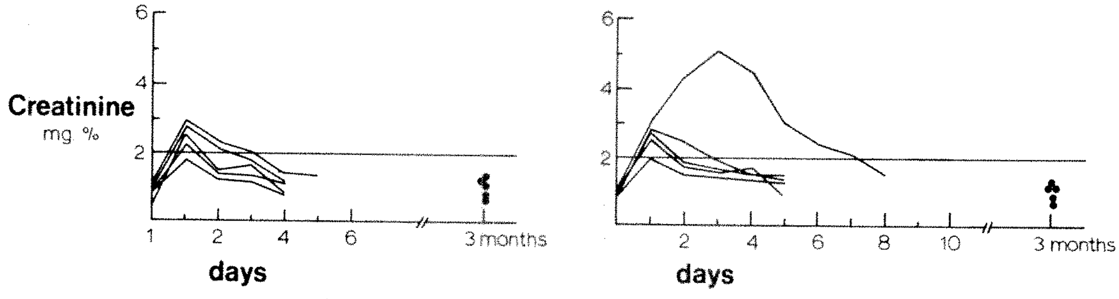

FIG. 2.—Kidneys preserved for 24 hours without warm ischaemia. A, By Collins's method. B, By continuous hypothermic perfusion.

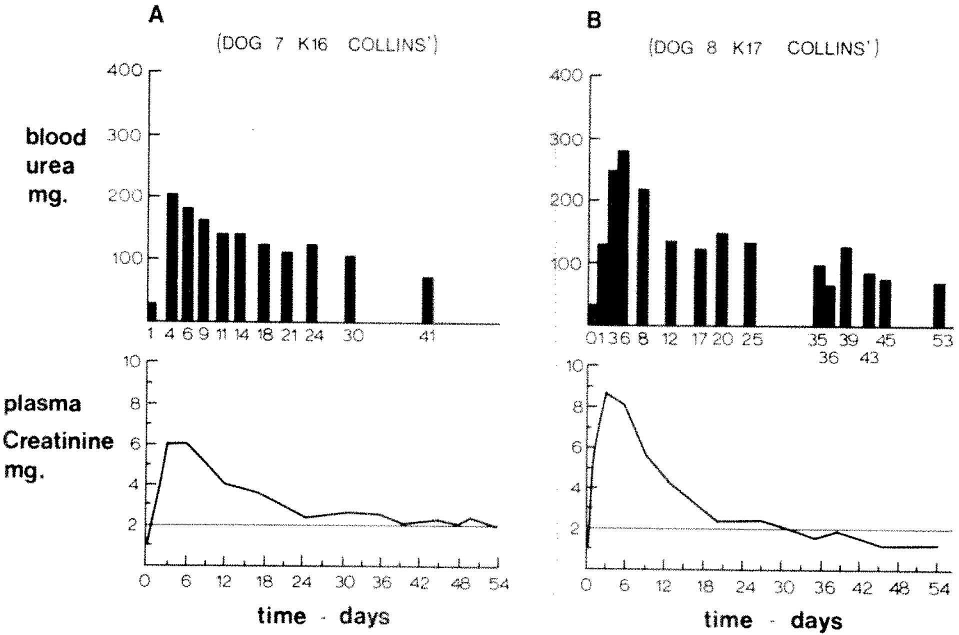

FIG. 3.—Kidneys preserved by Collins's method after 30 minutes of warm ischaemia, with delayed contralateral nephrectomy.

b. Continuous Perfusion with P.P.F.$_{(1)}$ *at 6° C., with Delayed Contralateral Nephrectomy (Table V).*—Seven kidneys had up to 40 minutes of warm ischaemia; all returned rapidly to normal function after delayed contralateral nephrectomy. The plasma-creatinine levels commonly rose during the first 3 days; the highest value was 4·6 mg. per cent, but in every instance the plasma-creatinine level was normal by the seventh day.

Table V.—RESULTS OF 24-HOUR PRESERVATION USING P.P.F.$_{(1)}$, WITH DELAYED CONTRALATERAL NEPHRECTOMY

WARM ISCHAEMIA TIME	NO. OF DOGS	NO. OF SURVIVORS	PERCENTAGE SURVIVING	MEAN NO. OF DAYS TO REACH BIO-CHEMICAL NORMALITY	
				Creatinine	Urea
15	2	2	100	< 5	< 12
30	5	5	100	10	25
40	2	2	100	10	25
60	3	2	66·6	8	25
100	1	—	—	—	—
180	3	—	—	—	—

c. Continuous Perfusion with P.P.F.$_{(2)}$ at 6° C., with Immediate Contralateral Nephrectomy.—Six kidneys were preserved by continuous hypothermic perfusion with P.P.F.$_{(2)}$ at 6° C. The kidneys all became pink on reimplantation. Five made urine immediately. Though all 6 dogs survived immediate contralateral nephrectomy postoperatively plasma-creatinine levels rose to high peaks (maximum, 12 mg. per cent; *Fig.* 4) and there was a delay of up to 14 days before all had returned to normal function.

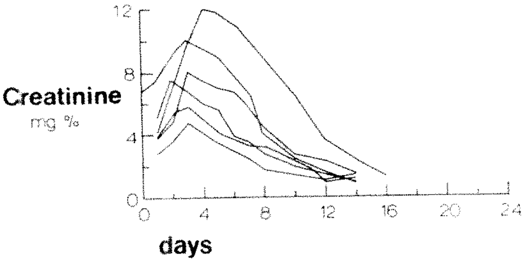

FIG. 4.—Kidneys preserved by continuous perfusion for 24 hours after 30–40 minutes of warm ischaemia, with immediate contralateral nephrectomy.

Recovery of function was heralded by a marked increase in urinary output between the second and fourth postoperative days. Two dogs became quite dehydrated as a result of this diuresis and required support with subcutaneous Ringer's lactate.

Group III: Kidneys preserved for 24 Hours after 60–180 Minutes of Warm Ischaemia (*Table V*).—All the kidneys in this group were preserved by continuous perfusion with P.P.F.$_{(1)}$ at 6° C. Three kidneys received 60 minutes of warm ischaemia; all 3 became pink on revascularization but none made urine. Two dogs survived delayed contralateral nephrectomy and their transplanted kidneys resumed completely normal function. The third dog was killed on the fifth postoperative day. Histology of the kidney showed cortical necrosis.

Four kidneys had warm ischaemic intervals of 100–180 minutes. None of these functioned and all 4 had cortical necrosis.

Group IV: Kidneys preserved for a Short Preliminary Period in Ice followed by Continuous Hypothermic Perfusion with P.P.F.$_{(2)}$ to 24 Hours.—

a. No Warm Ischaemia.—Three kidneys were stored in ice for 6 hours and then removed from ice and placed on the perfusion circuit and perfused for a further 18 hours (*Fig.* 5). All 3 kidneys supported life following immediate contralateral nephrectomy, but the postoperative plasma-creatinine levels were much higher than in those kidneys preserved without warm ischaemia by perfusion alone or by ice storage alone. The highest recorded creatinine was 6 mg. per cent.

b. Thirty Minutes' Warm Ischaemia (*Table VI*).—

i. Four kidneys were stored for 3 hours in ice prior to perfusion. Three were immediately able to sustain life; the fourth dog died of renal failure.

ii. Eight kidneys were stored in ice for 6 hours prior to perfusion; 5 were immediately able to support life. Three dogs died of renal failure. The renal function in 1 of the survivors had not returned to normal even at 3 months (plasma creatinine, 2·8 mg. per cent; plasma urea, 110 mg. per cent).

The remaining 4 dogs all returned to biochemical normality. The highest plasma creatinine was 14 mg. per cent and the longest duration of abnormal function was 17 days.

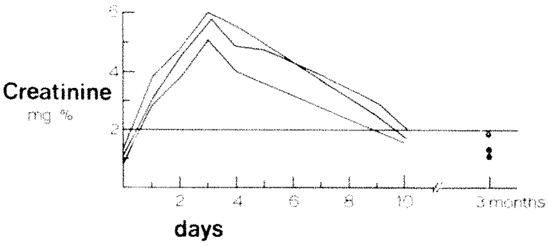

FIG. 5.—Kidneys preserved for 24 hours by the combined method of 6 hours of ice storage followed by 18 hours of perfusion without warm ischaemia, with immediate contralateral nephrectomy.

Table VI.—RESULTS OF 24-HOUR PRESERVATION AFTER 30 MINUTES' WARM ISCHAEMIA, WITH IMMEDIATE CONTRALATERAL NEPHRECTOMY

GROUP	NO. OF DOGS	NO. OF SURVIVORS	MEAN NO. OF DAYS TO REACH BIOCHEMICAL NORMALITY	
			Creatinine	Urea
Perfusion alone	6	6	7	23
3 hours in ice	4	3	9·6	25
6 hours in ice	8	5	9·9	25

Flow Characteristics.—

1. *Rate of Initial Wash-out.*—The time required to flush 200 ml. of fluid through the kidney by gravity infusion from 150 cm. increased progressively with the warm ischaemic interval, indicating an increase in renal vascular resistance (*Fig.* 6). Blood-staining of the venous effluent continued throughout the entire wash-out period in kidneys subjected to prolonged periods of warm ischaemia, whereas the venous effluent cleared rapidly when the warm ischaemic interval was short.

2. *Perfusion Pressure* (*Figs.* 7, 8).—The perfusion pressure of kidneys injured by 30–40 minutes of warm ischaemia was raised during the first hour when compared with uninjured kidneys (*Fig.* 7). This difference, however, failed to reach statistical significance. All the kidneys in these two groups functioned normally on reimplantation. When the perfusion pressures of those kidneys which failed to function on reimplantation were compared with the normal range (*Fig.* 8), it was found that only the initial reading was significantly different from normal ($0{\cdot}1 < P > 0{\cdot}05$); thereafter the pressure fell rapidly into the normal range.

Change in Weight.—All the kidneys gained weight during perfusion. The range of weight-gain for those kidneys which functioned immediately was 4–22 per cent. The range of weight-gain for those kidneys which failed to function was 5–24 per cent.

Change in Perfusate *p*H.—Kidneys which nctioned immediately after reimplantation were mpared with those which failed to function even en contralateral nephrectomy was delayed (*Fig.* 9). here was a highly significant difference between the o groups especially during the first hour of perfuon. Those kidneys which had been subjected to olonged warm ischaemia (1 hour or more) exhibited profound drop in *p*H during the first hour from 24 to 6·97 ± 0·04, whereas those kidneys which nctioned immediately exhibited only a very small ll in *p*H during the first hour from 7·25 to 7·15 ± 0·04. his difference was statistically significant (*t* = 4·3, '> 0·001).

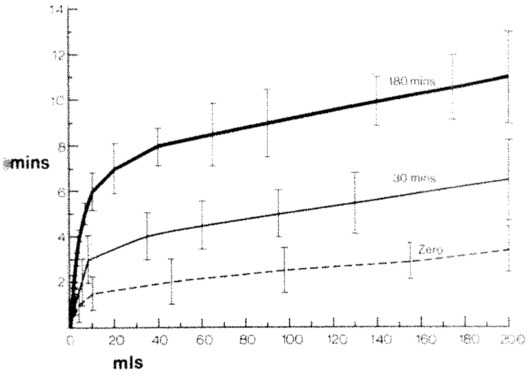

FIG. 6.—Rate of venous outflow during initial wash-out. ▬▬, 180 minutes of warm ischaemia (mean of 3). ——, 30 minutes of warm ischaemia (mean of 10). - - -, No warm ischaemia (mean of 10). All the results are ± 2 S.E.

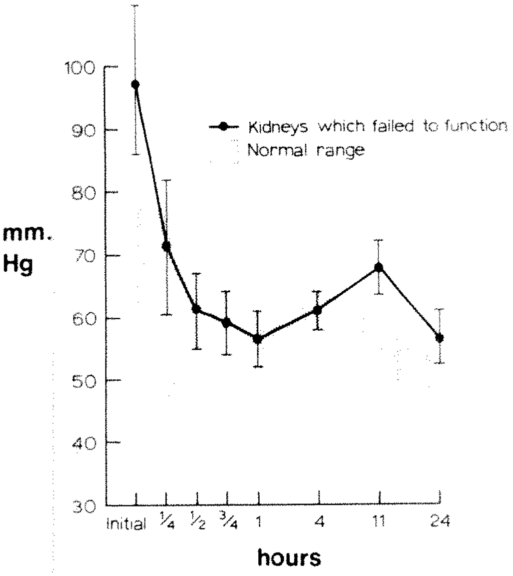

FIG. 8.—Change in perfusion pressure over 24 hours.

After the first hour the *p*H rose in both groups: in e survivor group the *p*H returned to normal at 24 ours; in the failure group the *p*H plateaued at 6·99 ± ·05 and then fell again to 6·9 ± 0·1 at 24 hours.

Perfusate L.D.H.—L.D.H. accumulation in the erfusion fluid was compared for those kidneys which functioned immediately and those which failed to function at all. The range of L.D.H. among the survivors was 190–512 I.U. compared with 376–419 I.U. for the failures. Although the failures were always in the 300–400 range there was no significant difference between the two groups.

DISCUSSION

When a warm ischaemic interval was excluded canine kidneys were preserved equally well by either simple ice storage using Collins's method or continuous perfusion with plasma-protein fraction. Postoperative plasma-creatinine levels followed very similar patterns and in neither group did they rise above 3 mg. per cent. These results confirm the findings of other worker in the field (Belzer and others, 1967; Collins and others, 1969; Collste, Bjorken, Collste, and Groth, 1970; Liu, Humphries, Russell, Stoddard, and Moretz, 1971).

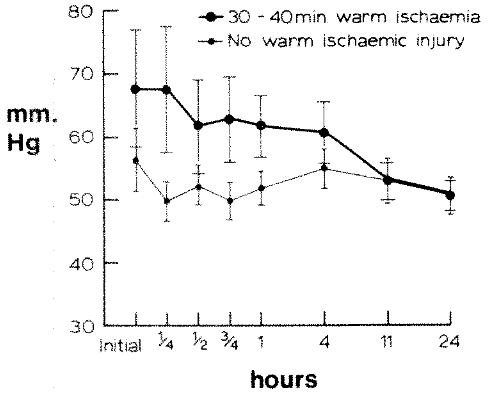

FIG. 7.—Change in perfusion pressure over 24 hours.

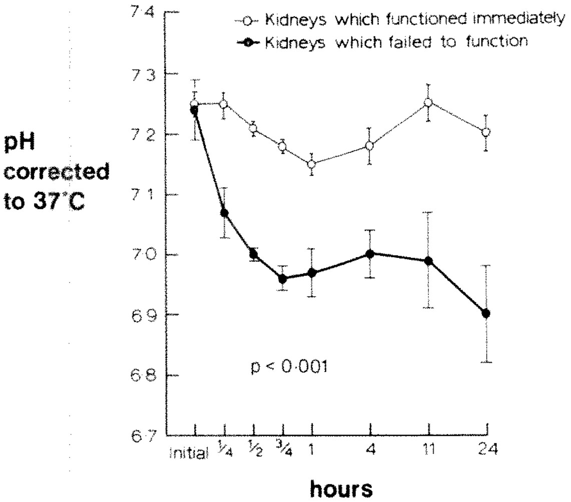

FIG. 9.—Changes in perfusate *p*H over 24 hours.

The introduction of a warm ischaemic interval of 30 minutes produced a very significant difference in the results obtained from these two preservation methods. Kidneys preserved by Collins's method either failed to function completely or were just able to sustain life even when protected by delayed contralateral nephrectomy, whereas using continuous perfusion kidneys returned to normal function after up to 60 minutes of warm ischaemia when protected by delayed contralateral nephrectomy. A warm ischaemic interval of 40 minutes was compatible with immediate life-sustaining function after 24-hour perfusion.

Simple ice storage by Collins's method followed by continuous perfusion can be used to give 24-hour preservation with immediate return of function in kidneys injured by 30 minutes of warm ischaemia. However, the quality of immediate postoperative renal function is not as good as when kidneys are preserved by perfusion alone, neither are the results so reliable. After 6 hours' ice storage only 5 out of 8 kidneys could sustain life and only 4 of the 5 returned completely to normal function. The duration of ice storage would appear to be critical; when it exceeds 6 hours, delayed return of function is the best result that can be expected.

What then is the effect of a warm ischaemic interval and how can it produce such a radical difference between two preservation methods which are well established for storing healthy kidneys?

We have observed that as the warm ischaemic interval increased there was a proportional increase in renal vascular resistance as evidenced by a diminished rate of flow of the initial wash-out solution, higher initial perfusion pressures, and increased blood-staining of the perfusate. There was also a fall in *p*H during the first hour of perfusion; this was most profound in those kidneys subjected to prolonged warm ischaemic injury. None of these kidneys functioned subsequently and the changes in perfusate *p*H that they exhibited differed very significantly from the *p*H changes of both fresh and ischaemically injured kidney that did function immediately ($t = 4 \cdot 3$, $P < 0 \cdot 001$). A fall in the surface *p*H of rabbit kidneys exposed to warm ischaemic injury has previously been reported (Dmochowski, Couch, Kempf, and Appleton, 1966; Couch, Maginn, Middleton, Appleton, and Dmochowski, 1967; Couch and Middleton, 1968), but because in most perfusion systems it is necessary to adjust the *p*H continuously in order to maintain stability of the perfusion solution a fall in the perfusate *p*H has not previously been correlated with function after transplantation.

The absence of oxygen precludes the utilization of the citric acid cycle and forces the renal cells to metabolize glucose in such a manner that only 8 per cent of the total potential energy available through the oxidation of glucose is released (White, Handler, and Smith, 1964). Without continuous perfusion marked suppression of aerobic metabolism occurs within minutes (Wilhelmi, Russel, Engle, and Long, 1945). The maintenance of cellular volume is an active energy-consuming process which is dependent on the active extrusion of sodium at the cell membrane (Leaf, 1959). Lack of energy causes pump failure which leads to accumulation of sodium and water in the cells and cellular swelling. The accumulation of lactic acid and the other by-products of anaerobic metabolism leads to a fall in *p*H which causes further cellular swelling. Cellular swelling and metabolic acidosis account for the increased vascular resistanc and for the profound fall in perfusate *p*H.

Simple hypothermia by suppressing metabolis also causes some cellular swelling; provided that th kidney is cooled rapidly this swelling is usuall minimal, but in the presence of established ischaem injury further periods of cold anoxia may have cumulative effect, whereas continuous hypotherm perfusion with an oxygenated energy-rich solutic should arrest and reverse anoxic injury by allowir aerobic metabolism to recommence even at a ver reduced rate and by washing out, diluting, an buffering the by-products of anaerobic metabolism.

In conclusion, continuous hypothermic perfusic with oxygenated plasma-protein fraction is the be way to preserve ischaemically injured kidneys. Up 60 minutes of warm ischaemia is compatible wit normal function after 24 hours' perfusion. Combin tions of up to 6 hours' ice storage and 18 hour perfusion are practicable but perfusion alone preferable.

A profound fall in *p*H during the first hour perfusion is a clear indication that the kidney irreversibly injured. This indication is reinforced the fall in *p*H is sustained or continues througho the 24-hour period.

Changes in perfusion pressure, kidney weight, an perfusate L.D.H. gave no indication of subsequer failure to function.

UBRETID®

distigmine bromide

maintains smooth muscle tone
prevents urinary retention or intestinal atony

UBRETID inhibits cholinesterase for a full 24 hours, giving prolonged improvement in smooth muscle tone. Thus, with minimum inconvenience to staff or patient, a normal pattern of micturition and defaecation can usually be re-established without the discomforts of catheters or enemata. Where indwelling catheters are unavoidable, **UBRETID** will maintain bladder tone, reduce residual urine volume and encourage normal bladder function when the catheter is withdrawn.
Full details of **UBRETID** ampoules and tablets are available upon request.

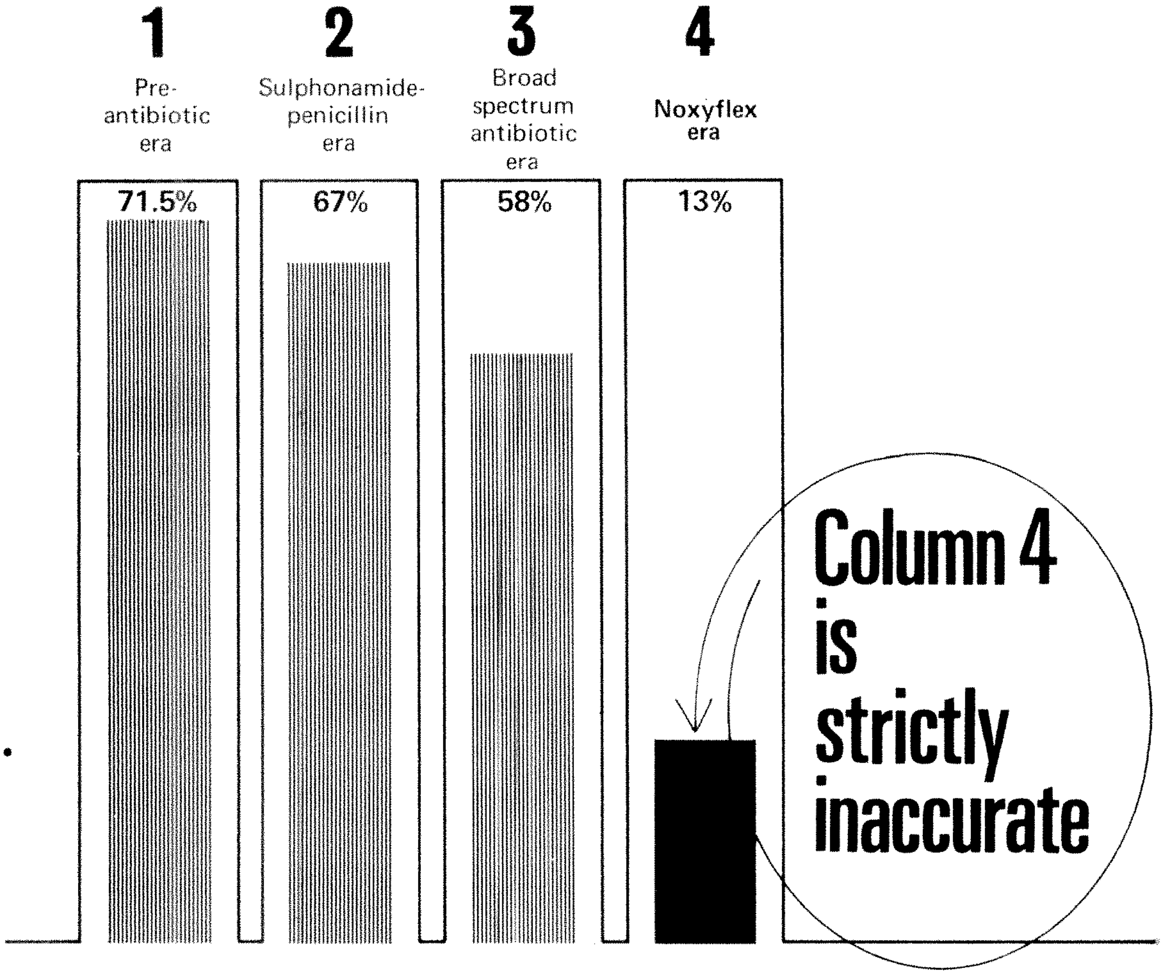
The graph below compares mortality rates due to faecal peritonitis, era by era.
It is not pedantically accurate because its sources differ. But the point is fairly made.



Why inaccurate? Because column 4 refers to 23 cases of faecal peritonitis which were treated successfully with Noxyflex. But the *3 deaths which occurred were due to causes other than peritonitis - as post-mortem revealed. **The mortality rate due to peritonitis can therefore be regarded as zero.**

* The whole graph, and the causes of the deaths referred to are the subject of the new Noxyflex folder "Why three deaths?" You will receive at least one copy!

When bacterial contamination of the peritoneum is diagnosed or suspected: Noxyflex

A MODEL WHICH CAN BE USED TO IMPROVE THE TREATMENT OF ACUTE HEPATIC FAILURE

By JOHN WINCH

DEPARTMENT OF SURGERY AND LIVER UNIT, KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, LONDON

SUMMARY

A model using the pig from which the liver has been removed for isolated perfusion, as a subject showing some of the features of acute hepatic failure for later treatment by cross-circulation with its own perfused liver, is described. Effects of such a procedure on the glucose and halothane metabolism and intravascular coagulation and bleeding are detailed.

THE main clinical problem with which the present paper is concerned is the treatment of a patient in fulminant hepatic failure. Such a patient, whether the necrotizing agent affecting the liver is the hepatitis virus or a chemical compound such as paracetamol, presents a challenging clinical syndrome (Trey and Davidson, 1970). The acute failure of the *excretory* function of the liver allows accumulation in the blood of bilirubin, ammonia and amino-compounds, and any natural or administered toxic substance whose route of excretion should involve the hepatic metabolism. The inexorable accumulation of such products leads to neurological disturbances, probably occurring first in the brain-stem reticular formation, producing coma (*Fig.* 1), progressing to depression of the respiratory and vasomotor centres, and finally leading to respiratory and cardiac arrest. The biochemical changes are as complex as the neurological abnormalities, with respiratory alkalosis, metabolic alkalosis (James, Nashat, Sampson, Williams, and Garassini, 1969) associated with loss of potassium, probable renal failure, and impairment of carbohydrate metabolism with hypoglycaemia (Leading article, 1971) associated with high levels of circulating insulin (Knell, Pratt, Curzon, and Williams, 1972). The failure of the synthetic function of the liver is reflected by a low serum albumin and a lowering of the circulating fibrinogen and all except Factor VIII of the coagulation factors. The bleeding tendency is worsened by the necrotic tissue in the liver acting as a focus for intravascular coagulation (Rake, Flute, Shilkin, Lewis, Winch, and Williams, 1971), thus adding a consumptive element to the bleeding tendency.

Much can be done to support the patient but there comes a stage when the patient is unconscious, on a ventilator, and tending to bleed from the slightest stimulus when the surgeon is called, for then the patient needs the benefit that can only come from a functioning extra liver. The rationale of such treatment lies in the remarkable powers of regeneration of the liver (Blumgart, Leach, and Karren, 1971), for if temporary liver function is provided for the patient (Winch, 1971) eventual regeneration of the patient's own liver may result in recovery. In this country the most easily available extra liver is that of the pig, although primate or cadaver human livers may prove to be better (Abouna, Serrou, Boehmig, Amemiya, and Martineau, 1970). In an earlier communication a circuit suitable for perfusing the pig liver with human blood was described and the biochemical evidence of adequate function of the liver was presented (Winch, Fleisher, Hague, Kolthammer, Bentley, Shilkin, and Williams, 1971). The next step was to develop a technique of cross-circulating an isolated perfused liver with a suitable subject.

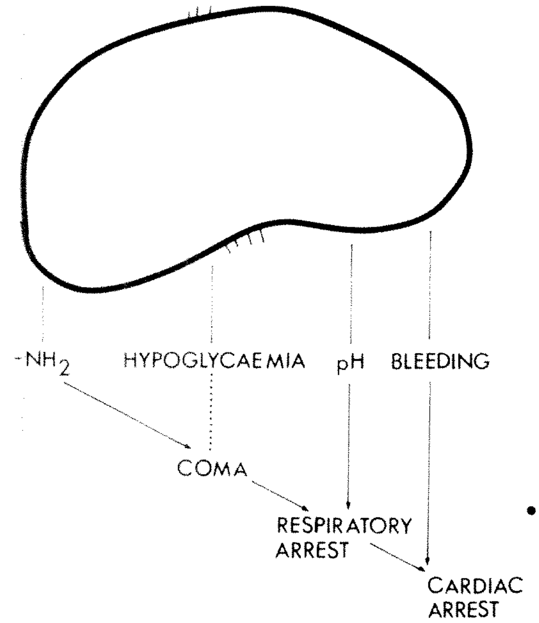

FIG. 1.—Clinical and metabolic consequences of fulminant hepatic failure.

The aims of the present study were therefore:—

1. To study the metabolic consequences of cross-circulation of a perfused pig liver with an animal which was preferably in hepatic failure.
2. To gain technical experience of such a cross-circulation.

CHOICE OF ANIMAL

It is difficult to produce the picture of human hepatic failure in an animal since the hepatitis virus does not affect animals and preparing a succession of animals with hepatic necrosis induced by chemical insult would be a major undertaking in itself. However, each time a pig liver was perfused in an isolated circuit directly after hepatectomy an animal was being discarded which because it had no liver should show a pure picture of hepatic failure, uncomplicated by the toxic overlay of the presence of a large mass of necrotic tissue.

It was therefore decided to retain the pig from which a liver was obtained for perfusion, to maintain it in an anhepatic state while the liver was being studied in an isolated circuit, and later to cross-circulate the pig with its own liver.

This paper reports three experimental periods (*Fig.* 2): first, the anhepatic pig and, secondly, the isolated perfused liver, both studied concurrently during 3 hours, and, thirdly, a period immediately following this when the liver was cross-circulated with the anhepatic pig for 1½ hours.

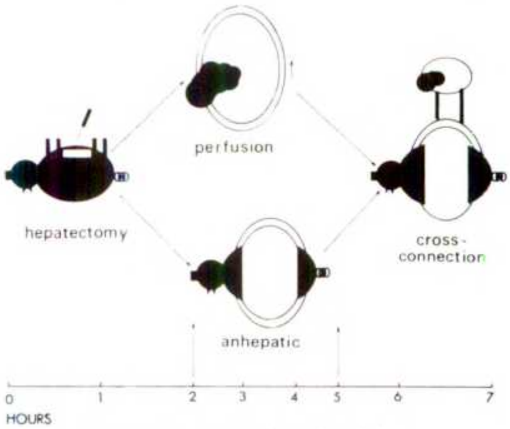

FIG. 2.—Plan of experimental periods.

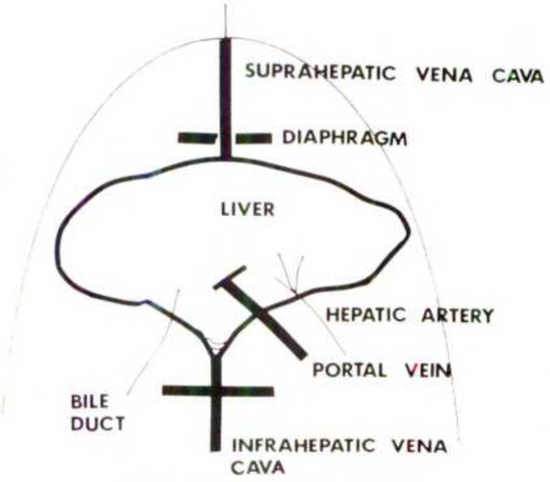

FIG. 4.—Liver prepared for removal.

THE NEEDS FOR A BY-PASS SHUNT

The first problem in developing this use of the anhepatic pig was that the pig (Terblanche, Peacock, Bowes, and Hobbs, 1968), like the calf (Battersby, Balderson, Winch, and Burnett, 1971), but unlike the monkey (Milnes and Child, 1949) or man (Starzl, Groth, Brettschneider, Penn, Fulginiti, Moon, Blandshard, Martin, and Porter, 1968), will not survive acute ligation of the portal vein. Pre-hepatectomy portacaval shunt would not provide a drainage for the portal system, for in the pig the inferior vena cava passes through the liver, thus necessitating removal of a long section of the vena cava during hepatectomy. An external shunt was therefore indicated which for ease of maintenance of circulation should be made to decompress the abdominal inferior vena cava as well as the portal vein.

The shunt that was designed (*Fig.* 3) consists of a short length of polyvinylchloride tubing (Portex, 9·5 mm. diameter) with two cannulae (Bardic venou cannula 1061/20) at one end, for the portal vein and ven cava respectively, and a cannula (Bardic 1060/18) at th other end for insertion into the right external jugula vein. This external shunt functioned well without an pump being necessary, giving a flow in excess o 250 ml. per minute into the external jugular vein Since two connecting points would later be needed i the pig for cross-circulation, two side-arms whic could be opened when cross-circulation was starte were added to the shunt.

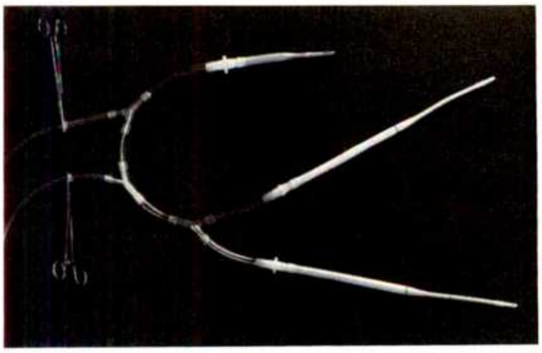

FIG. 3.—By-pass shunt for the portal vein and the intrahepatic vena cava. No external pump was necessary. Note the connexions for later cross-circulation.

ANAESTHESIA AND MONITORING CANNULAE

Each experiment began with induction of anaesthesia in a 20-kg. pig by means of halothane and snout mask. This was followed by endotrache intubation and maintenance of anaesthesia with halothane administered by intermittent positive-pressur respiration. A short vertical incision was then mad in the neck to cannulate the right internal jugular vei for a slow dextrose infusion and a central venou pressure manometer. The right common caroti artery was cannulated to provide continuous blood pressure monitoring. The right external jugular vei was exposed for later cannulation with the upper en of the by-pass shunt. Heparin, 5000 U., was give intravenously to prevent coagulation in the cannula or shunt.

PREPARATION FOR HEPATECTOMY

Through a midline abdominal incision the fir structure to be identified and cannulated was th common bile-duct, which was allowed free drainag during the subsequent operative procedures. Th gall-bladder was isolated by ligation in continuity the cystic duct. The liver was then dissected free of a except its main vascular connexions (*Fig.* 4): the ver cava was defined just above the right adrenal vein, th liver was dissected free of the diaphragmatic crura posteriorly, and the diaphragm was opened to expose the vena cava above the liver, taking care to ligate the large phrenic veins. The portal vein was exposed and the large pancreatic and splenic tributaries were tied, with particular dissection well into the pancreatic tissue to provide placement for the decompressing portal vein shunt. The common hepatic artery was similarly exposed and all the branches to the pancreas, duodenum, and stomach were ligated. During the whole of this procedure the circulation of the liver was not obstructed.

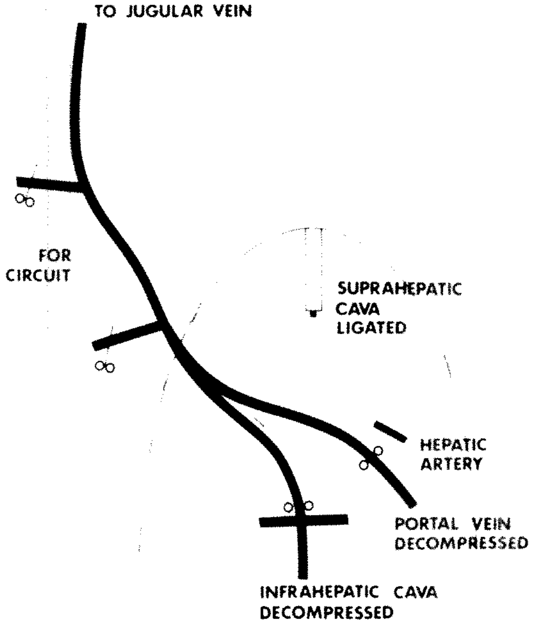

FIG. 5.—By-pass shunt in place after hepatectomy.

COMPLETION OF HEPATECTOMY AND INSERTION OF A BY-PASS SHUNT

When the preliminary work was completed the by-pass shunt was primed with saline and the upper end was inserted into the external jugular vein. The vena cava below the liver was cannulated in the direction of the hind-legs by one half of the lower end of the shunt (*Fig.* 5). The caval by-pass was then opened and the vena cava below the liver was clamped and divided. The portal vein was cannulated in the direction of the liver to enable cooling of the liver to begin with an infusion of a balanced solution of electrolytes (approaching intracellular concentration), heparin, and Rheomacrodex at 7° C. The pancreatic side of the portal vein was cannulated with the other half of the by-pass shunt, the shunt was opened, and the portal vein was divided. The common hepatic artery was then clamped and divided and the only remaining vascular connexion, the suprahepatic vena cava, was dealt with similarly.

TECHNIQUE OF ISOLATED PERFUSION

Flushing of the liver was continued outside the abdomen while the hepatic artery and the vena cava below the liver were cannulated. The vena cava above the liver was ligated, taking care not to obstruct the hepatic veins. The fully prepared liver could now be transferred to float in the saline which forms the physical support for the liver in this circuit (*Fig.* 6). The perfusate was fresh, heparinized pig blood buffered with bicarbonate and allowed to flow into the liver as an oxygenated supply through the portal vein under gravity and through the hepatic artery in a pulsatile manner, with a total flow through the liver of 1 ml. per g. of liver per minute. A solution of mixed bile-salts was infused into the circuit at a constant rate to compensate for the interrupted enterohepatic circulation of bile-salts. The first 30 minutes of isolated perfusion were spent in slowly rewarming the liver to 38° C. Warm perfusion was then continued for 3 hours.

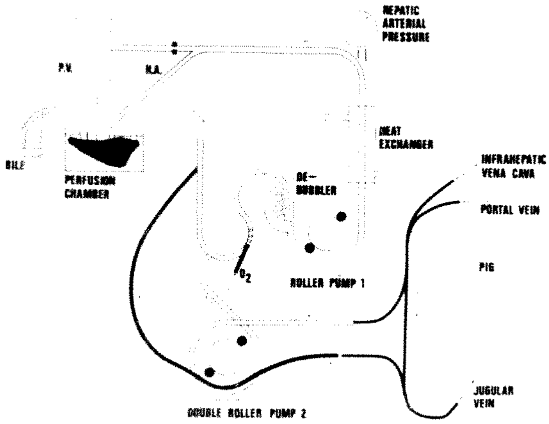

FIG. 6.—Circuit diagram for isolated perfusion and cross-circulation. Liver circulation is provided by pump 1, while cross-circulation is effected independently by pump 2.

MAINTENANCE OF THE ANHEPATIC PIG

The first three attempts to maintain the pig alive after hepatectomy failed largely because of technical difficulties in swiftly cannulating the portal vein in opposite directions. However, once the technique was mastered, maintenance was possible with constant monitoring of the arterial and central venous pressure.

TECHNIQUE OF CROSS-CIRCULATION

Cross-circulation was prepared simply by unclamping the cross-connecting lines and starting the second (double-headed) pump (*Fig.* 6). The speed of the second pump was increased to the maximum flow in both directions that was possible without the flow in the midpart of the by-pass shunt reversing (i.e., up to the maximum flow that was emerging from the combined portal vein and inferior vena cava); this was usually 250 ml. per minute. The main pump in the circuit remained at a constant speed throughout the cross-circulation (usually 900 ml. per minute), for the circuit design allows the flow into the liver to be independent of the flows to and from the anhepatic pig.

The first attempt at cross-circulation was followed within a few minutes of the start by a dramatic fall in the blood-pressure of the anhepatic pig. Cardiac arrest occurred shortly after. Resuscitation with internal cardiac massage and intravenous calcium was possible, and it was observed that the pig's blood-pressure could be titrated against the rate of calcium infusion. This provided a clue to the cause of cardiac arrest and subsequent analysis revealed that the pig's serum potassium at the time was well over 8 mEq./l. This high level derived from the high level in the liver circuit, which in turn derived from loss from the liver substance during the ischaemic period of preparation (Abouna, 1968) and in part from the flushing solution still remaining in the liver at the time of connexion to the circuit. After this experiment the first 350 ml. of blood which had passed through the liver were discarded when isolated circulation was begun. From then on no further technical problems were encountered and 11 successful studies were performed with this model.

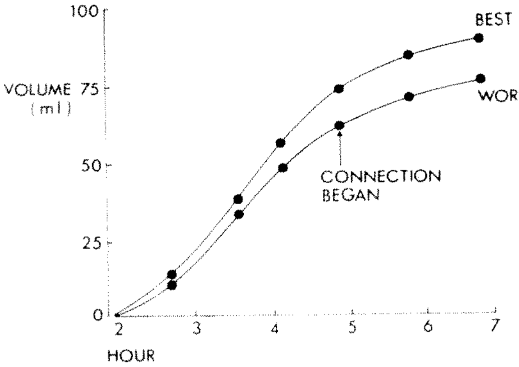

FIG. 7.—Cumulative bile volumes produced by the perfused liver. Bile continued to flow during cross-circulation.

Table I.—BIOCHEMICAL ASSESSMENT OF THE PERFUSED LIVER

GROUP	BILE VOLUME (ml. per 3 hr.)	$T_{\frac{1}{2}}$ BSP IN PERFUSATE (min.)	BSP IN BILE (percentage of loading dose)	$T_{\frac{1}{2}}$ GALACTOSE IN PERFUSATE (min.)
Isolated perfused liver: (n = 11)	45 ± 11·9	67 ± 21	62 ± 12·3	18 ± 10·8
Intact pig (n = 6)	75 ± 17·3	10 ± 2·8	70 ± 13·8	11 ± 5·9

All the results are given as the mean ± S.D.

ASSESSMENT OF LIVER FUNCTION

Excretion in the Perfused Liver.—The biochemical function of the isolated liver was assessed by its ability to deal with administered doses of 100 mg. bromsulphthalein (BSP) and 5 g. of galactose as well as by the rate of bile production. The rates of disappearance of both BSP and galactose from the perfusate were calculated by estimation of serial samples taken from the circuit, to give an indication of the ability of the liver to take up these substances from the blood circulating through it. After uptake BSP is stored, some is conjugated, and both conjugated and free forms are excreted into bile (Whelan, Hoch, and Combes, 1970). The amount of BSP that was excreted into the bile produced during the 3-hour perfusion was also measured to give perhaps a more valid estimate of liver function than does uptake alone (Ham, Pirola, and Elmslie, 1969). Figures for these biochemical assessments are shown in *Table I* together with comparative figures obtained in other studies with intact anaesthetized pigs. The function of the isolated liver is adequate but is less than that in the intact pig where there has been no hepatectomy and cannulation to produce ischaemia. These figures compare well with reduction to two-thirds of the intact liver values that have been reported by other workers (Tygstrup, Funding, Juul-Nielsen, Keiding, Kondahl, Ramsöe, and Winkler, 1971). The only indication of continuing biochemical activity of the perfused liver during cross-circulation was the rate of bile-flow which continued in all the experiments (*Fig.* 7) at an acceptable rate.

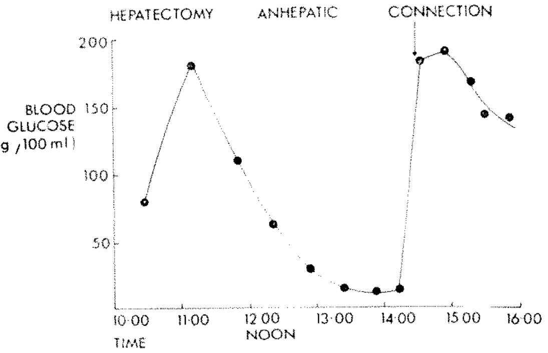

FIG. 8.—Blood-glucose in the pig during one typical experiment. Glucose is infused during hepatectomy but not thereafter.

Excretion in the Anhepatic Pig.—The period (3 hours) of the anhepatic phase was too short to allow accumulation of any detectable amounts of bilirubin or amino-compounds in this series.

Glucose.—The amount of glucose in the perfusate of the isolated liver was maintained at a high level throughout the perfusion without the addition of exogenous glucose. In the anhepatic pig there was a rapid and profound fall in blood-glucose (*Fig.* 8) which remained at extremely low levels until corrected by cross-circulation. There are at least two major factors contributing to this hypoglycaemia of the anhepatic pig: absence of production of glucose by the liver and lack of uptake by the liver of insulin, allowing excessive insulin action peripherally. Correction of the hypoglycaemia by cross-circulation could be due to restoration of either or both of these deficiencies. At least part of the rise was due to the high level of glucose existing in the circuit, but continued normal levels during the 1½-hour period of cross-circulation suggested active liver function.

Synthetic Function of the Liver.—Evidence of synthesis of albumin and fibrinogen by the liver in both the circuit and the pig was sought during the study but no significant changes were found. This reflects either the slower metabolic turnover of protein compared with that of glucose or that protein synthesis was more affected by the less efficient function of the isolated lever compared with that of a normal liver.

EFFECT OF HALOTHANE ON THE ANHEPATIC PIG

One other indication of liver function was obtained virtually as a by-product of the experimental method. Anaesthesia was maintained in the pig by the administration of halothane carried in oxygen and nitrous oxide through a ventilator. The depth of anaesthesia was monitored indirectly by observing the effect of halothane on the pig's blood-pressure—a very sensitive indicator. Excess halothane causes a rapid fall in pressure, while too little allows the blood-pressure to rise and the pig begins to awake from anaesthesia. During hepatectomy continuous administration of halothane was necessary (*Fig.* 9) but within minutes of hepatectomy being complete evidence of halothane excess was seen by a falling blood-pressure. This could only be prevented by stopping the administration of halothane completely during the anhepatic phase. A few minutes after cross-circulation was started the animal began to awake unless halothane administration was recommenced.

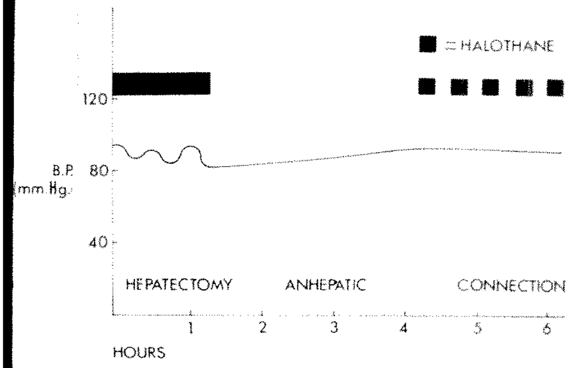

FIG. 9.—Halothane requirements for adequate anaesthesia during the experiments. The blood-pressure is satisfactory throughout. No additional halothane is required after the completion of hepatectomy until the liver is reconnected to the pig.

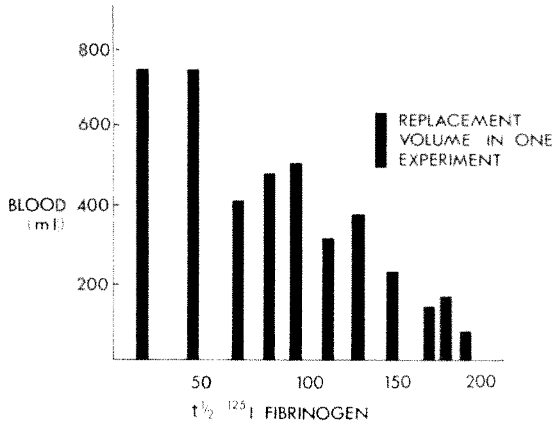

FIG. 11.—Volume of blood required to replace loss from the pig during cross-circulation compared with estimations of intravascular coagulation in the perfused liver using ^{125}I-fibrinogen.

Previously halothane was regarded as a metabolically inert anaesthetic but some 20 per cent of the administered dose has been shown to be metabolized (Rehder, Forbes, Alter, Hessler, and Stier, 1967), as indicated by the urinary appearance of metabolites. The present observations suggest that the site of this metabolism is the liver and the need for less halothane in the cross-circulation period than for the intact pig again reflects the reduction in efficiency of the isolated liver.

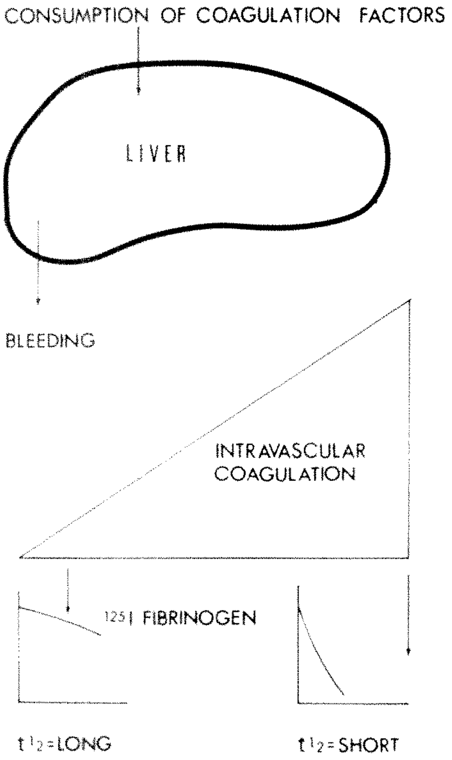

FIG. 10.—Intravascular coagulation in the perfused liver indicated by the disappearance of ^{125}I-fibrinogen from the perfusate.

INTRAVASCULAR COAGULATION IN THE PERFUSED LIVER AND ITS EFFECT ON THE ANHEPATIC PIG

Each isolated liver was assessed during perfusion for the occurrence of intravascular coagulation by the administration of ^{125}I-fibrinogen (10 μc.) to the perfusate and by serial sampling to estimate its rate of disappearance. This has previously been demonstrated to be a useful method of assessment of the likely effects on the recipient's coagulation state if the perfused liver were to be used for cross-circulation (Winch and others, 1971). A rapid fall in the labelled fibrinogen indicates excessive intravascular coagulation, which in turn would lead to bleeding when the recipient's coagulation factors were consumed once cross-circulation was begun (*Fig.* 10).

In the series of cross-circulations presented here there was often considerable bleeding from the cut surfaces in the anhepatic pig, beginning shortly after cross-circulation commenced. To maintain circulation additional blood was required. The amount of blood needed was more when there was a short $T_{\frac{1}{2}}$ of ^{125}I-fibrinogen (*Fig.* 11), indicating significant intravascular coagulation, than when a longer $T_{\frac{1}{2}}$ was found.

This relationship of bleeding to intravascular coagulation as indicated by ^{125}I-fibrinogen agrees with previous theoretical predictions.

CONCLUSION

The use of the model described has fulfilled the two aims of the present work, in that efficient cross-circulation of a functioning isolated liver with an animal having absent hepatic function and a study of the metabolic effects of such a procedure have been carried out. The perfused liver restores glucose metabolism to the anhepatic pig when cross-circulation is performed. The use of this model also suggests hepatic metabolism of halothane, which earlier was regarded as being metabolically inert. Theoretical ideas concerning intravascular coagulation and bleeding were supported, and a need to reduce the circulating potassium in the perfusion circuit before using the method on a patient was discovered. Further work is required to study the method of preparation of the perfused liver, such that its function more nearly reaches that existing before hepatectomy and cannulation cause deterioration. This is necessary in order that the full possible benefit of temporary hepatic function may be offered to a patient in fulminant hepatic failure.

REGRESSION OF AXILLARY LYMPH-NODES IN CANCER OF THE BREAST

By M. H. EDWARDS,* M. BAUM,† and C. J. MAGAREY‡

DEPARTMENT OF SURGERY, KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, LONDON

SUMMARY

A multicentre, prospective trial on the treatment of Stage-I and Stage-II breast cancer by simple mastectomy plus radiotherapy versus simple mastectomy alone is described. So far 1050 patients have been collected within 2 years. Data on the first 161 patients treated by simple mastectomy alone are analysed. Axillary lymph-nodes have regressed within 3 months of mastectomy in 75 per cent of patients in clinical Stage II. Regression may be due to resolution of reactive changes in lymph-nodes following removal of the primary tumour.

Cancer of the breast is the commonest malignant disease in women in the United Kingdom, but we still do not know with certainty which form of treatment at present confers benefit on the patient, which has little effect, or which may be harmful (Editorial, 1969). Experience indicates that only prospective, randomized clinical trials are likely to provide firm facts upon which rational decisions can be based. Few such clinical trials have been carried out (Brinkley and Haybittle, 1966; Easson, 1968; Kaae and Johansen, 1968; Fisher, Slack, Cavanaugh, Gardner, and Ravdin, 1970). In all these trials it was assumed that treatment to the regional lymph-nodes was necessary, reflecting a radical approach based on a traditional view of the spread of cancer of the breast. It is believed that malignant disease is autonomous and spreads centrifugally through the surrounding tissues, along lymphatic pathways to the local lymph-nodes, and at a later stage by the blood-stream to form distant metastases. Therefore, if the breast and regional lymph-nodes are treated effectively patients in whom the tumour has not spread further should be cured, but treatments of a lesser degree should fail in a greater proportion of patients. All radical types of treatment are justified by this concept of cancer spread. No significant differences so far have been detected in th overall survival rates when any two radical treatments have been compared (Brinkley and Haybittle, 1966; Easson, 1968; Kaae and Johansen, 1968; Fisher and others, 1970).

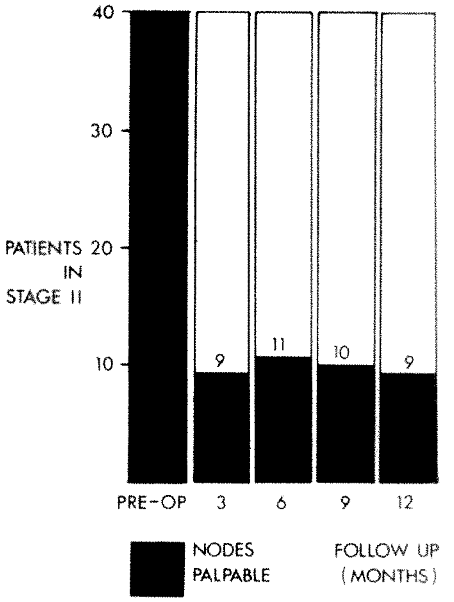

FIG. 1.—Progress of axillary lymph-nodes in 40 patients in Stage II.

In recent years evidence has been accumulating in support of a more conservative approach to treatment. In the Manchester trial (Easson, 1968) radical mastectomy with postoperative radiotherapy was compared with radical mastectomy alone. In the latter régime no treatment was given to the internal mammary nodes and yet the survival rate in this group of patients was similar to that in the group which did receive treatment to the nodes. Again, Crile (1968) reported a series in which patients fared as well without axillary clearance as those treated with axillary clearance. There is some evidence that routine treatment of regional lymph-nodes by radiotherapy may even reduce the survival rate (Bond, 1967). The assumption that there is a moment in time when metastases from a breast tumour have not spread beyond the local tissues has been strongly challenged by the findings of Galasko (1971). At least 20 per cent of patients with apparently early breast cancer have significant bony metastases demonstrable by scintiscanning. It is not unlikely that tiny foci of tumour cells are already present throughout the whole body at the time of detection of the primary tumour. Abundant evidence, mainly from animal sources, suggests that the body plays an active part in the control of tumour growth and that the reticulo-endothelial system may be largely responsible (Fisher, 1971). Indeed, Gewant, Chasin, Tilson, Rutledge, and Goldenberg (1972) have shown that in breast-cancer patients the axillary lymph-nodes show a definite activity *in vitro* against the presence of the primary tumour. It may well be important to preserve lymphatic tissue even in the presence of microscopic deposits of tumour.

As a result of widespread doubts about the value of radical treatment and the lack of precise information about the results of conservative measures, a large prospective clinical trial supported by the Cancer Research Campaign was launched in 1970 to compare a radical with a conservative régime in a methodical and scientific manner (Edwards, Baum, Magarey, and Myson, 1971).

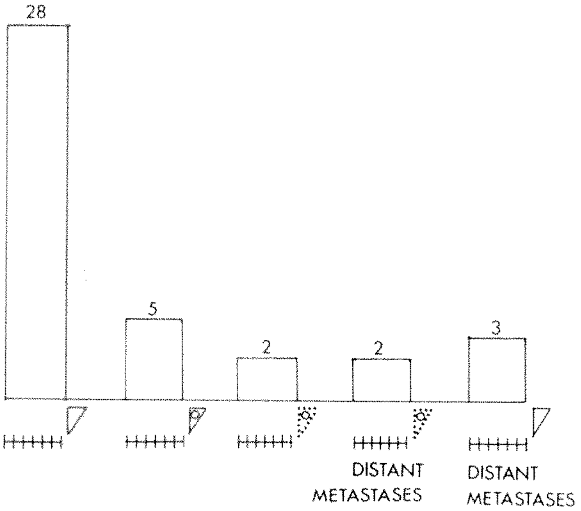

FIG. 2.—Progress of 40 patients in Stage II.

Simple mastectomy followed by routine irradiation to the regional lymphatic field was chosen as the best example of an established and widely used form of radical treatment (Editorial, 1969). It was to be compared with the conservative treatment of simple mastectomy alone with preservation of the regional lymph-nodes. The lymph-nodes would not be treated in the latter régime unless there was evidence of local progression of the disease. This conservative régime represents a fresh approach to the management of early breast cancer, and participants and critics alike are awaiting the first comparative results which will be available in 2–3 years. However, there is particular interest in the fate of the lymph-nodes which have not been treated. It is the purpose of this paper to describe the early progress of patients in the conservative treatment group.

PATIENTS

Women under the age of 70 years with Stage-I and Stage-II (T_1+T_2, N_0+N_1, M_0) breast cancer are eligible for the trial. A standardized simple mastectomy is performed on all patients. The procedure consists of removing the whole breast including the axillary tail while avoiding deliberate excision of the axillary lymph-nodes. After operation the patients are divided randomly into two groups. In one, the *irradiated group*, a standardized course of radiotherapy is given to the skin-flaps and the axillary, supraclavicular, and internal mammary lymph-node areas. In the second, the *'watch policy' group*, no treatment is given to the regional lymph-nodes after simple mastectomy unless there is evidence of progression of the disease. In this group there is no intention of allowing lymph-nodes to progress to the extent that symptoms may arise. The criteria which are regarded as evidence of active growth of tumour in nodes include progressive enlargement and the development of fixation.

All the patients are examined at 3-monthly intervals and clinical information including the presence or absence of local lymph-nodes and recurrences is recorded. Any other initial treatment, such as oophorectomy or the administration of hormones or cytotoxic drugs, is not permitted.

In the first 22 months of the study 1050 patients have been accepted from 85 centres in the United Kingdom, Eire, Scandinavia, Switzerland, and New Zealand. Over 2000 patients are expected to have been included by 1973. It has now been agreed that comparisons will be made with patients in the National Surgical Adjuvant Breast Project in the United States of America.

RESULTS

So far, 161 patients in the 'watch-policy' group have have been followed up for a period of 12 months and the results are available for study.

Of 40 patients judged to be in Stage II, in no less than 75 per cent the axillary lymph-nodes have regressed (*Fig.* 1). The regression was apparent at the first follow-up examination 3 months after mastectomy and has persisted. In 5 patients (*Fig.* 2) the nodes remained palpable but unchanged, and in 2 patients treatment has been given for progressive enlargement of lymph-nodes in the absence of distant metastases. In 5 other patients distant metastases have developed but only in 2 of them was treatment required for axillary node progression.

Of 121 patients in Stage I, 11 patients had palpable axillary nodes which have not progressed during the first year of follow-up (*Fig.* 3). In addition, 4 patients have received treatment for progression of axillary lymph-nodes in the absence of distant metastases. Seven patients have developed distant metastases with or without lymph-node progression, and of these 7, 3 patients have died.

DISCUSSION

There has always been doubt about the prognostic significance of palpable axillary nodes in patients with carcinoma of the breast and uncertainty about how to treat them. The fact that in the present trial the great majority of palpable nodes have regressed following simple mastectomy (Stage II reverting to Stage I) highlights this dilemma.

There is evidence that the enlargement is due to sinus histiocytosis in about one-third of lymph-nodes (Black and Speer, 1958). It may be that a proportion of the nodes which undergo spontaneous regression do so because of the removal of the tumour and consequently the stimulus to the sinus histiocytosis. There is increasing evidence that such changes in th regional lymph-nodes may be part of a defenc mechanism, helping to contain the malignant growth to some extent (Editorial, 1969). Again, it may be that the defence mechanism involved the reticulo-endothelial system as a whole and that the regional lymph-nodes are only part of this mechanism. Radiotherapy, as it is traditionally employed following simple mastectomy, interferes not only with the function of the regional lymph-nodes but also with other aspects of the reticulo-enthothelial system (Magarey and Baum, 1970) and if this is so then routine postoperative radiotherapy to the regional lymph-nodes may be harmful in a proportion of patients (Editorial, 1969).

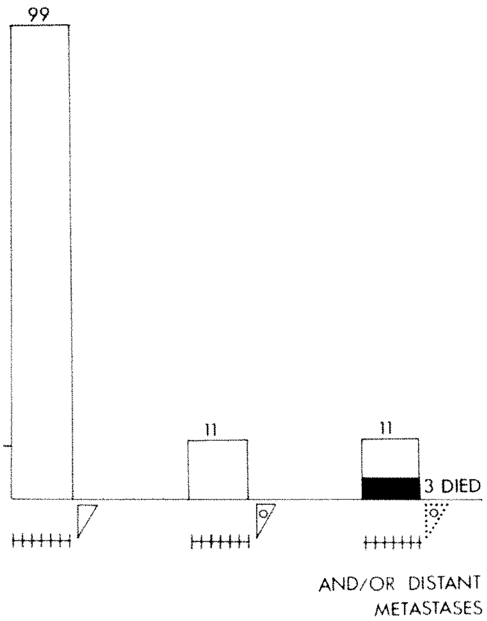

FIG. 3.—Progress of 121 patients in Stage I.

On the other hand, histological studies of radical mastectomy specimens show that in 50 per cent of patients with palpable lymph-nodes there is metastatic disease in the axillary nodes (Wallace and Champion, 1972). Thus a proportion of the nodes in the present study which have regressed are likely to contain malignant cells. Is it possible that under certain circumstances some of these lymph-nodes containing malignant cells are still capable of exerting some protective process against further growth of these cells? The present trial, for the first time, compares a radical form of treatment involving radiotherapy with a conservative approach without radiotherapy. Only with a longer follow-up and larger numbers of patients within this trial will the dilemma be resolved.

Acknowledgements.—We are very grateful to Professor J. S. Mitchell, Professor J. G. Murray, and over 300 clinicians for their support and encouragement.

IN BRONCHITIS early optimism confirmed by further clinical experience

❝On the basis of our earlier experience,[1] we said of trimethoprim that 'we believe it to represent a major discovery and to have far-reaching therapeutic possibilities.' Not only have we had no subsequent reason to alter this belief, but in our view some very promising possibilities have yet to be explored.❞[2]

More effective than ampicillin or tetracycline

In the reduction obtained in sputum volume and purulence SEPTRIN* has been shown to be superior to either ampicillin or tetracycline.[3,4]

Highly active against both primary and secondary invaders

". . . not only are the two primary pathogens *Strep pneumoniae* and *H influenzae* sensitive, but so are secondary invaders such as klebsiella which often replace them after antibiotic treatment."[2]

"It is seldom at the completion of a clinical trial that authors are inclined to classify an antimicrobial . . . , but in this case, on our results, we feel that the combination of trimethoprim plus sulphamethoxazole can only be considered excellent on the criteria originally specified, namely the elimination of the infecting microorganism."[5]

KEEPING THE STERILE FIELD STERILE

—that is the objective of patient drapes in theatre

BARRIER* Theatre Drapes — unlike absorbent cotton drapes — are treated to resist strike-through of fluids — thus reducing the risk of bacterial transfer to the open wound.

BARRIER* Theatre Drapes also provide a number of other advantages:—

* Drapes are folded, cuffed and marked for convenient, aseptic handling.

* A full range of both composite and single item drape sets are available for the majority procedures.

* Presented in both sterile form and for inclusion in hospital prepared packs.

* Complemented by an advanced and unique drape system of absorbent/repellent adhesive towels.

* Completely disposable, reducing the work load in service departments and eliminating associated laundry problems.

THE VALUE OF PRESERVING THE PYLORUS IN THE SURGERY OF DUODENAL ULCER

BY C. S. HUMPHREY AND A. R. WILKINSON

UNIVERSITY DEPARTMENT OF SURGERY, THE GENERAL INFIRMARY AT LEEDS

SUMMARY

Highly selective vagotomy without a drainage procedure (H.S.V.) has been used in the surgical treatment of 120 cases of duodenal ulcer in Leeds over the past 3 years. In this operation preservation of the vagal nerve-supply to the antral region of the stomach permits preservation of an intact pylorus. In the present paper the results which have been achieved are assessed, both clinically and experimentally, by comparison with the results in patients after truncal or selective vagotomy and pyloroplasty at a comparable stage after operation.

Studies of gastric emptying provide no evidence of gastric stasis after H.S.V., and symptoms of flatulence and food vomiting are found no more frequently than after vagotomy and pyloroplasty. After both truncal and selective vagotomy and pyloroplasty gastric emptying and small-bowel transit were abnormally fast, whereas after H.S.V. there was much less departure from the values found in preoperative ulcer patients. At the clinical and experimental level dumping and diarrhoea were significantly less frequent after H.S.V. than after vagotomy and pyloroplasty.

To date there has been no operative mortality, no case of recurrent ulcer, and no reoperation for gastric stasis after H.S.V. Preservation of a more normal pattern of gastric emptying, by reducing the incidence of dumping, diarrhoea, and bile vomiting, has led to better overall (Visick) results after H.S.V. than after truncal or selective vagotomy and pyloroplasty.

THERE is now considerable evidence that many of the sequelae of gastric surgery which may mar otherwise good results arise from abnormalities of gastric emptying (Colmer, Davies, Owen, and Shields, 1969; McKelvey, 1970; Cobb, Bank, Marks, and Louw, 1971). The operation of highly selective vagotomy without a drainage procedure (H.S.V.) (Johnston and Wilkinson, 1970) combines an effective attack on the acid- and pepsin-secreting proximal part of the stomach with an attempt to preserve the mechanisms which normally control gastric emptying. This is achieved by denervating the parietal cell mass of the stomach and preserving, in addition to the hepatic and coeliac branches of the vagus, the parasympathetic nerve-supply to the antrum of the stomach—the nerves of Latarjet. No drainage procedure is added to this vagotomy so that an intact and innervated antrum, pylorus, and duodenum are left to regulate gastric emptying.

H.S.V. has been performed in 120 patients with chronic duodenal ulcer in Leeds over the past 3 years. This paper attempts an assessment of this operation by comparing and contrasting the results obtained with those found after the conventional operations of truncal and selective vagotomy with pyloroplasty performed in the same surgical unit.

MATERIALS AND METHODS

Clinical Study.—The clinical results are derived from the assessment made at the Gastric Follow-up Clinic at Leeds. The patients were interviewed by a panel of surgeons and physicians who were unaware of the nature of the operations the patients had undergone until after they had reached an agreement. In this way an unbiased assessment was possible. Follow-up data 1–2 years after operation were available for 62 patients who had undergone H.S.V. for duodenal ulcer. These results were compared with the results 1–2 years after bilateral selective vagotomy and pyloroplasty in 67 patients, and the results 2 years after truncal vagotomy and pyloroplasty in 158 patients; the latter results have already been published from this unit (Goligher, Pulvertaft, de Dombal, Clark, Conyers, Duthie, Feather, Latchmore, Matheson, Harrop-Shoesmith, Smiddy, and Willson-Pepper, 1968). In order to achieve a greater degree of objectivity in the assessment of symptoms of alimentary dysfunction 50 patients who had undergone appendicectomy, herniorrhaphy, or varicose-vein operations 1 year previously were included in the Gastric Follow-up Clinic without the prior knowledge of the interviewing panel. These patients constitute the control series.

Experimental Studies.—A number of experimental studies have been performed to obtain more precise information about gastric emptying and small-bowel transit time and to highlight any differences which might exist in the liability to such symptoms as dumping and diarrhoea. The patients chosen for these studies were representative of the larger groups with respect to individual symptoms and overall Visick grading. Patients with duodenal ulcer before operation were also investigated as a control group. The numbers of patients in each study are indicated in the results.

Diarrhoea	22	19	3

T.V. + P., Truncal vagotomy with pyloroplasty. S.V. + P., Selective vagotomy with pyloroplasty. H.S.V., Highly selective vagotomy without a drainage procedure.

Hypertonic Glucose Meal.—This consisted of 350 ml. of a 25 per cent solution of glucose to which phenol red had been added to a concentration of 250 parts per million. Gastric emptying was measured by the percentage of the test meal leaving the stomach in 20 minutes, the method and calculations being based on the test described by George (1968). Similar tests were performed with the patients standing upright and without aspiration of the stomach in an attempt to provoke the onset of dumping and diarrhoea.

Food and Barium Meal.—A standard meal of toast and butter, scrambled eggs, and a cup of tea was homogenized with 30 ml. of barium suspension to a semi-fluid consistency. The serial radiographs taken after eating this were reviewed by an experienced radiologist who was not aware which operation had been performed. Gastric emptying has been expressed in terms of whether the stomach was completely empty by 90 minutes after the start of the meal, and small-bowel transit time by whether the head of the meal had reached the caecum in this time interval.

RESULTS

Clinical Study.—The individual symptoms recorded at the Gastric Follow-up Clinic 1–2 years after operation are shown in *Table I.* The incidence of dumping and diarrhoea—symptoms which are related to abnormally rapid gastric emptying—is shown in *Fig.* 1, whilst *Fig.* 2 shows the incidence of flatulence and food vomiting. There is no evidence that H.S.V. is followed by more flatulence or food vomiting than is vagotomy and pyloroplasty. Both dumping and diarrhoea, particularly the latter, have been reduced in incidence by H.S.V. It is noteworthy that bile vomiting has not been recorded after this operation, whilst the incidence is about 10 per cent after both truncal and selective vagotomy and pyloroplasty.

The overall clinical grading is shown in *Table II* and *Fig.* 3. The incidence of outright failures (Visick grade 4) is similar after each of the operations at 8–12 per cent. However, the incidence of Visick grade 3 results (unsatisfactory clinical results because of severe symptoms of alimentary dysfunction which cannot be controlled by modifications of diet) is much less after H.S.V., only 6 per cent of the patients falling into this category compared with 25 per cent after vagotomy and pyloroplasty. By reducing the incidence of symptoms such as dumping, diarrhoea, and bile vomiting H.S.V. has led to a considerable increase in the number of good and excellent results (*Fig.* 3).

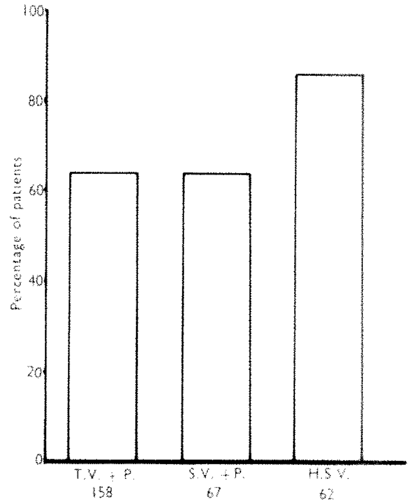

FIG. 3.—Proportion of good to excellent clinical results (Visick I and II) 1–2 years after operation.

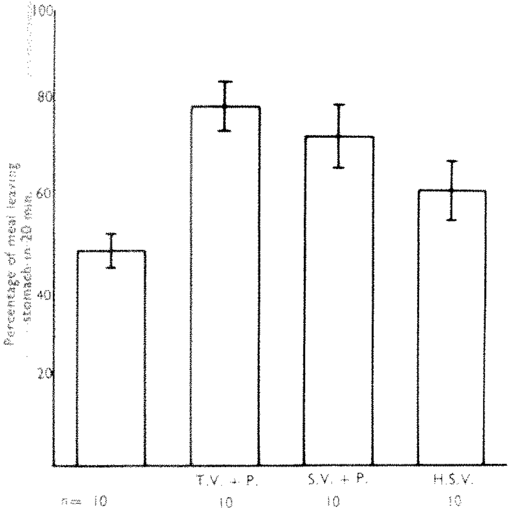

FIG. 4.—Gastric emptying of hypertonic glucose: percentage of meal leaving the stomach in 20 minutes. Mean ± 1 S.E.M.

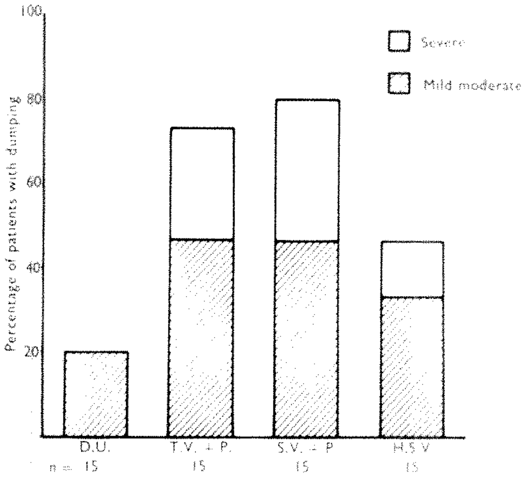

FIG. 5.—Incidence of dumping after the ingestion of hypertonic glucose.

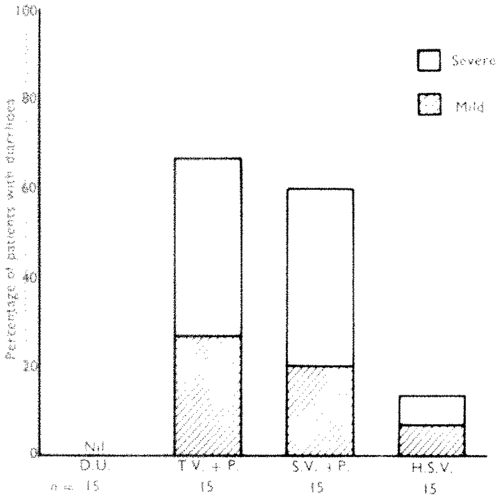

FIG. 6.—Incidence of diarrhoea after the ingestion of hypertonic glucose.

Experimental Studies.—

Gastric Emptying of a Fluid Meal.—The mean percentage of the test meal leaving the stomach in 20 minutes is shown in *Fig.* 4. After both truncal and selective vagotomy and pyloroplasty significantly greater amounts of the meal left the stomach than in the preoperative ulcer patients ($P < 0{\cdot}05$). Although the rate of emptying was faster in the H.S.V. patients than in the preoperative patients, it was not significantly so.

When the same meal was drunk without aspiration of the stomach, the onset of dumping and/or diarrhoea was provoked in a proportion of patients. The incidence of dumping and diarrhoea after oral glucose is shown in *Figs.* 5 and 6. Both dumping and diarrhoea occurred significantly more frequently after vagotomy and pyloroplasty than after H.S.V. ($P < 0{\cdot}02$).

Food and Barium Meal.—The percentage of patients whose stomachs had emptied within 90 minutes of eating the meal is shown in *Fig.* 7. Gastric emptying of this semi-fluid meal was significantly faster than in the preoperative patients after both truncal ($P < 0.002$) and selective ($P < 0.01$) vagotomy and pyloroplasty but not after H.S.V. Small-bowel transit time was significantly reduced after all three operations when compared with the preoperative patients. The head of the meal had reached the caecum in 36 per cent of the patients after H.S.V. ($P < 0.03$) compared with 60 per cent after selective vagotomy ($P < 0.01$) and 83 per cent after truncal vagotomy ($P < 0.001$).

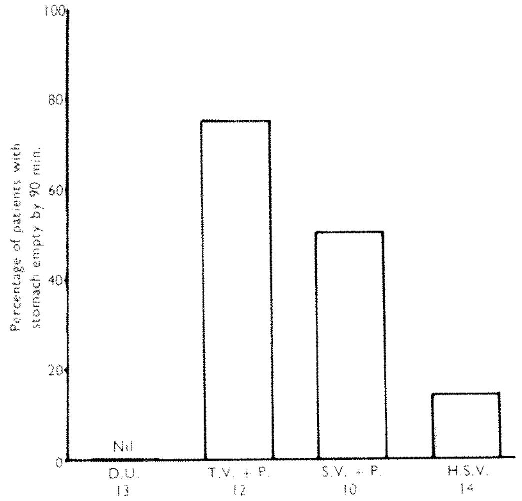

FIG. 7.—Gastric emptying of food and barium meal: percentage of patients with complete emptying of the stomach by 90 minutes.

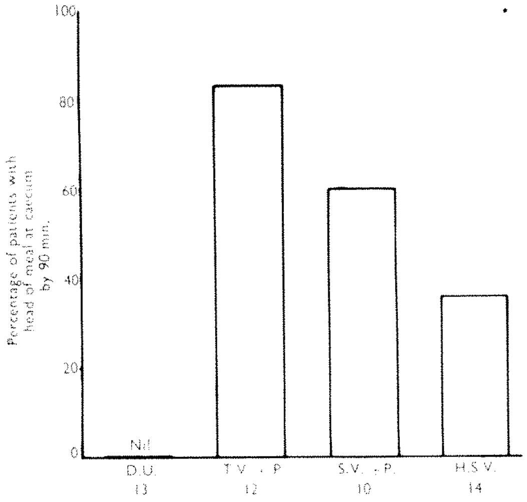

FIG. 8.—Small-bowel transit of food and barium meal: percentage of patients in whom the head of the meal had reached the caecum by 90 minutes.

DISCUSSION

One defect of the present study must be admitted at the outset, namely that the results obtained are not derived from a prospective randomly controlled clinical trial. However, the operations were all performed in the same surgical unit where the indications for operation have not changed. Moreover, the results have been assessed in a 'blind' manner by a panel, so that we feel that any advantages we have shown for one operation are more likely to be due to differences between the operations themselves rather than to dissimilarities in the patients coming to operation.

An operation for chronic duodenal ulcer which preserves the pylorus and deliberately retains an innervated antrum must be examined critically on two counts: recurrent ulceration and gastric stasis. H.S.V. has been performed on more than 250 patients in Leeds and Copenhagen (Amdrup, 1972) over the past 3 years without a single recurrent duodenal ulcer to date. Holle (1969) has performed more than 300 proximal selective vagotomies with either pyloroplasty or antrectomy and reports a recurrent ulcer rate of only 7 per cent. There is no reason to expect that H.S.V. will be followed by a higher incidence of recurrent ulceration than vagotomy and pyloroplasty since basal acid output, maximal acid output to pentagastrin, and peak acid output to insulin are all reduced as effectively by H.S.V. as by truncal or selective vagotomy (Johnson and Wikinson, 1970; Wilkinson, Humphrey, Mason, Smith, and Johnston, 1971). The innervated antrum does not lead to an excessive release of gastrin in response to meat extract (Johnston, Humphrey, Smith, and Wilkinson, 1971).

Even though H.S.V. has been performed on some patients with considerable scarring of the duodenum we have not had to reoperate on any patient for gastric retention. Symptoms of gastric stasis, flatulence, and food vomiting do not occur more frequently after H.S.V. than after vagotomy and pyloroplasty. The studies of gastric emptying are particularly reassuring as they show that gastric emptying of both fluid and semi-fluid meals is slightly more rapid than in the preoperative patient. Omission of a drainage procedure does not lead to gastric stasis, provided that the propulsive power of the gastric antrum is retained.

The studies of gastric emptying of hypertonic glucose confirm previous reports (George, Connell, and Kennedy, 1968; Hall and Read, 1970; McKelvey, 1970) that a fluid meal leaves the stomach more rapidly after vagotomy and drainage than in the preoperative subject. Indeed, as McKelvey (1970) has so aptly put it, after vagotomy and pyloroplasty the stomach is incontinent of a fluid meal. This picture of uncontrolled gastric emptying is not seen after H.S.V. Moreover small-bowel transit time is nearer to normal after H.S.V. than after vagotomy and pyloroplasty. Preservation of the pylorus—more properly the antropyloroduodenal segment—enables controlled emptying to occur from the stomach. The corollary of this is that the incidence of unpleasant alimentary side-effects is reduced by H.S.V., leading to an increase in the proportion of good to excellent clinical results. These findings are in agreement with the observations of others that preservation of the pylorus after partial gastrectomy is accompanied by a better pattern of gastric emptying and fewer side-effects (Friesen and Rieger, 1960; Killen and Symbas, 1962; Amdrup, Nielsen, and Jensen, 1970; Hennessy, Weir, and D'Auria, 1972).

A gradation may be observed in both the physiological changes in gastric emptying and the incidence of the side-effects of operation, from the 'normal' preoperative stomach, through highly selective and selective vagotomy, to truncal vagotomy. It seems, not unreasonably, that the more that gastro-intestinal anatomy and physiology are unnecessarily interfered with, the worse may be the side-effects of surgery. H.S.V. does not give perfect results. For instance, one-third of the patients experience epigastric fullness which in some necessitates a reduction in the size of meals. However, by restricting the surgical attack to the acid- and pepsin-secreting part of the stomach only and by preserving all other parts H.S.V. seems to achieve a cure for ulcer dyspepsia without imposing too high a price in terms of 'post-vagotomy' symptoms.

SHORT PAPERS

PYLOROPLASTY ALONE IN THE MANAGEMENT OF PATIENTS WITH A NEGATIVE EXPLORATION FOR DUODENAL ULCER

BY M. DOUGLAS AND H. L. DUTHIE
UNIVERSITY DEPARTMENT OF SURGERY, ROYAL INFIRMARY, SHEFFIELD

SUMMARY

If a preoperative diagnosis of duodenal ulcer is not confirmed at laparotomy an exploratory pyloroduodenotomy may be closed as a pyloroplasty without adding a vagal section. This study concerns 32 patients in whom this was done. As a group these patients tended to have somewhat atypical ulcer symptoms and indefinite radiological signs. Within a mean follow-up period of 3½ years more than one-third of these patients developed recurrent ulcer symptoms, which in 4 patients to date have been successfully treated by vagotomy. The functional result could not be predicted by the preoperative symptoms or radiological changes. The incidence of diarrhoea and post-cibal fullness, vomiting, dumping, colic, and hypoglycaemia was almost identical with that seen after vagotomy and pyloroplasty. The wisdom of using pyloroplasty without vagotomy in patients with ulcer symptoms is therefore questioned.

THE inability to confirm at laparotomy a previously diagnosed duodenal ulcer is an uncommon but recurring problem. Because of the well-established risk of unpleasant sequelae there is a reluctance to submit these patients to what may be unnecessary ulcer surgery. Weinberg, Sempien, Movius, and Dnagadi (1956) advocated inspection of the mucosa of the duodenal cap and pyloric canal via a longitudinal incision, and if no sign of ulcer disease was found closing this as a pyloroplasty without proceeding to vagal section. However, little attention has been given to the long-term results of this policy or to the incidence of side-effects, although pyloroplasty alone has been used in the past for the treatment of duodenal ulcers (Horsley, 1926; Judd and Nagel, 1927) and more recently for gastric ulcers (Gilchrist, 1956; Farris and Smith, 1961).

In the present report the functional result in patients who underwent pyloroplasty without vagotomy after negative exploration for duodenal ulcer is assessed. These patients are compared with a matched group of patients who had a complete truncal vagotomy and pyloroplasty to establish the relative incidence of post-cibal symptoms.

MATERIALS AND METHODS

During the 6½ years from October 1964 to March 1971, 595 patients have undergone surgical treatment for duodenal ulcer in the Department of Surgery, Sheffield. Thirty-two of these patients had a Heineke-Mikulicz pyloroplasty performed without vagal section after exploration failed to confirm the presence of a duodenal ulcer or scar. These patients formed the study group. They were matched for sex, age, and length of time from operation with patients who had a Heineke-Mikulicz pyloroplasty and complete truncal vagotomy. The vagotomy was deemed complete if two insulin tests were negative by Hollander's criteria 2 weeks and 6 months respectively after surgery.

The patients were randomized and interviewed by a person who was unaware of the nature of the patients' operations. An assessment was made of the functional state according to a modification of the Visick classification (Visick, 1948). Careful inquiry was made as to the presence, frequency, and severity of side-effects attributable to the surgery. Symptoms were recorded only if they occurred at least three times a year. The following definitions were used:—

Dumping: Weakness, faintness, trembling, and sweating within 30 minutes of a meal. Severity was judged by whether patients had to sit or lie down and the time taken for recovery.

Diarrhoea: Three or more loose bowel actions in 1 day.

Hypoglycaemia: Weakness, faintness, trembling, sweating, and hunger occurring 2–4 hours after a meal.

Ulcer Symptoms: The presence of post-prandial epigastric pain, other than central abdominal colic, was taken as evidence of failed treatment. In view of the difficulty in making an absolute radiological or fibre-optic diagnosis of recurrent ulcer after pyloroplasty, clinical assessment only was used in this follow-up.

The case notes of all the patients were scrutinized in the same random order without knowledge of the type of operation, and an assessment was made of the preoperative clinical and radiological evidence for duodenal ulcer disease. Note was only taken of symptoms specifically recorded as being present or absent. Radiological features were taken from the original barium-meal reports.

RESULTS

All the patients were interviewed except 1 who had moved from the area and who was assessed by correspondence with the surgeon attending him.

The composition of the study group was similar to that of the matched vagotomized patients (*Table I*).

Preoperative Clinical State.—There were several differences between the two groups regarding the nature of the pain. By every criterion the patients in whom no ulcer was found tended to have less typical symptoms. This difference was statistically significant with regard to past or present relief of pain with food or alkali and to radiation of pain through to the back (*Table II*). In each group 4 patients with a history of haematemesis or melaena had required blood transfusion. The incidence of vomiting was not significantly different for the two groups. Preoperative acid studies revealed a lower mean output in the study group (34·0 mEq. per hour) than in the vagotomized group (43·5 mEq. per hour) although this difference was not significant.

Table I.—COMPOSITION OF THE GROUPS STUDIED

	Pyloroplasty	*Vagotomy and Pyloroplasty*
No. of patients	32	32
Male : female ratio	25 : 7	25 : 7
Age at operation (yr.)	42·6	45·0
Duration of symptoms (mth.)	118	130
Length of follow-up (mth.)	46·5	39·3

Table II.—PREOPERATIVE SYMPTOMS

SYMPTOM	PYLOROPLASTY		VAGOTOMY AND PYLOROPLASTY	
	No. of Patients	Per cent	No. of Patients	Per cent
Episodes of remission				
Absent	9	33·3	3	10·0
Present	18	66·7	27	90·0
Pain related to meals				
Absent	9	31·0	3	16·7
Present	20	69·0	25	83·3
Relief with alkali*				
Absent	8	27·6	1	3·1
Present	21	72·4	31	96·9
Pain at night				
Absent	11	37·9	5	15·6
Present	18	62·1	27	84·4
Back pain**				
Absent	20	74·1	11	36·7
Present	7	25·9	19	63·3
Haematemesis and melaena				
Absent	18	60·0	21	65·6
Present	12	40·0	11	34·4

Patients are only included where a symptom was specifically recorded as being absent or present.

* $\chi^2 = 5·42$, degrees of freedom = 1, $P < 0·025$.

** $\chi^2 = 6·58$, degrees of freedom = 1, $P < 0·01$.

Table III.—PREOPERATIVE RADIOLOGICAL CHANGES

RADIOLOGICAL CHANGES	PYLOROPLASTY		VAGOTOMY AND PYLOROPLASTY	
	No. of Patients	Per cent	No. of Patients	Per cent
No changes or irritable duodenal cap	8	25	0	
Mild deformity	8	25	3	9·4
Moderate deformity or probable ulcer crater	8	25	15	46·9
Gross deformity or definite ulcer crater	8	25	14	43·7
Total	32		32	

Radiological Evidence.—The reports of the examining radiologists were classified according to the degree of changes noted. Normal findings or 'irritable' duodenal cap were classed as no change and gross deformity or a definite ulcer crater as marked hange. Varying degrees of deformity or suggestion of an ulcer crater were classed as mild or moderate hanges. Those patients with a negative exploration had significantly less severe changes (*Table III*). The mean length of time from barium meal to operation was virtually identical in the two groups, being 6·7 and 6·3 months for pyloroplasty alone and for vagotomy and pyloroplasty respectively. However, in those 8 patients with marked changes but a negative exploration this delay was somewhat longer at 8·7 months (2 weeks to 2 years).

Table IV.—FUNCTIONAL RESULTS ACCORDING TO THE VISICK CLASSIFICATION

GRADE	PYLOROPLASTY		VAGOTOMY AND PYLOROPLASTY	
	No. of Patients	Per cent	No. of Patients	Per cent
	10	31·3	14	43·8
	6	18·8	9	28·1
a	4	12·5	8	25·0
b	0		0	
	12	37·5	1	3·1
Total	32		32	
Good (grades 1 and 2)	16	50	23	71·9
Satisfactory (grade 3a)	4	12·5	8	25·0
Poor (grades 3b and 4)	12	37·5	1	3·1
Total	32		32	

Comparison between the individual grades showed a significant difference. $\chi^2 = 11{\cdot}90$, degrees of freedom $= 3$, $P < 0{\cdot}01$.

Table V.—ANALYSIS OF POOR RESULTS

Symptoms	*No. of Patients*
Pyloroplasty	
Ulcer symptoms leading to vagotomy	4
Recurrent or persistent ulcer symptoms	5
Melaena (also a major preoperative symptom)	1
Daily vomiting (also a major preoperative symptom)	2
Total	12
Vagotomy and pyloroplasty	
Recurrent ulcer symptoms	1

Table VI.—DETAILS OF PATIENTS HAVING A SECONDARY VAGOTOMY

No. of patients	4
Symptom-free period after pyloroplasty (mth.)	4 (range, 2–6)
Period between pyloroplasty and vagotomy (mth.)	24 (range, 13–32)
Length of follow-up since vagotomy (mth.)	27 (range, 10–37)
Functional result (No. of patients)	
Good	3
Satisfactory	1

Postoperative Assessment.—The patients having pyloroplasty alone after a negative exploration fared badly according to the Visick classification (*Table IV*). The difference between the two groups was significant and a similar result was noted when grades 1 and 2 were grouped together. No patient in either group fell into grade 3b, which is also regarded as a poor result. Clinical evidence only was used to classify patients with poor results as even at reoperation it is often impossible to distinguish between scarring due to pyloroplasty and that due to recurrent ulceration (*Table V*).

Further details and the subsequent functional result of the 4 patients who underwent secondary vagotomy are shown in *Table VI*.

Postoperative Non-dyspeptic Symptoms.—The overall incidence of symptoms usually associated with vagotomy and drainage was virtually the same after pyloroplasty alone and after pyloroplasty and complete truncal vagotomy (*Table VII*). Apart from 2 patients who had persistent daily vomiting, in no case were the symptoms disabling. Where there was a clear difference in the severity of symptoms the more severe ones, e.g., episodic diarrhoea, tended to occur in the vagotomized group.

Table VII.—POSTOPERATIVE SYMPTOMS

SYMPTOM	PYLOROPLASTY (28 patients)		VAGOTOMY AND PYLOROPLASTY (32 patients)	
	No. of Patients	Per cent	No. of Patients	Per cent
Fullness	13	46·4	11	34·4
Vomiting	4	14·5	2	6·3
Colic	4	14·5	4	12·5
Diarrhoea	5	17·9	7	21·9
Dumping	4	14·5	8	25·0
Hypoglycaemia	4	14·5	6	15·6

Comparison between the two groups revealed no significant difference for any symptom.

Table VIII.—CORRELATION OF THE FUNCTIONAL RESULT WITH THE PREOPERATIVE EVIDENCE FOR DUODENAL ULCER

FUNCTIONAL RESULT	CLINICAL EVIDENCE		RADIOLOGICAL EVIDENCE	
	Weak	Strong	Weak	Strong
Good and satisfactory (Visick grades 1, 2, and 3a)	8	12	8	12
Poor (Visick grade 4)	5	7	8	4
	13	19	16	16

Comparison between those with weak evidence and those with strong evidence for duodenal ulcer showed no significant difference in the incidence of poor results.

Correlation of Postoperative Results with Preoperative State.—The 32 patients who had pyloroplasty alone were classified according to the features of their pain as listed in *Table II*. They were then grouped according to whether the clinical evidence for duodenal ulcer was weak or strong. The poor results were equally divided between these two groups (*Table VIII*).

A similar comparison was made using the radiological features. Although more of those with weak evidence for ulcer did poorly than those with strong evidence, this difference was far from significant (*Table VIII*).

Preoperative acid studies were available for 20 of the 32 patients and the proportion of poor functional results was similar whether the output was greater or less than 25 mEq. per hour (40 per cent and 30 per cent respectively).

DISCUSSION

The problem of the disappearing ulcer is far from negligible, arising in 5·3 per cent of all clinically diagnosed duodenal ulcers requiring surgical treatment in our department. This incidence is somewhat unreal because of the retrospective nature of the study. It was not possible to determine whether all the patients who received definitive ulcer surgery had signs of ulcer disease demonstrable at operation. Similarly the patients were not classified preoperatively although obviously the diagnosis of duodenal ulcer was made with varying degrees of conviction.

The matched group of vagotomized patients was included to avoid bias in the postoperative assessment and to afford a comparison of postoperative side-effects. The incidence of preoperative symptoms and radiological signs is in accord with common experience. In comparison, the study group tended to have atypical symptoms and less definite radiological changes, which possibly reflects a heterogeneous composition.

The patients who had pyloroplasty alone did very badly, with 37·5 per cent poor functional results. The matched group of vagotomized patients did rather better than an unselected series. This was due to the low risk of recurrent ulcers by virtue of the completeness of their vagotomy. They were probably further selected in that submitting successfully to two intubations (insulin tests) would tend to eliminate some 'unsatisfied' patients.

Could the poor results achieved by pyloroplasty alone be anticipated? It seems reasonable to speculate that those patients in whom no ulcer was found at operation may have consisted of several subgroups. First, there are those who had true ulcer disease which was missed at surgery because of healing without noticeable scarring or because of a post-bulbar position. Up to one-half of such patients could be expected to develop recurrent ulcer if their course was to parallel that after gastro-enterostomy alone (Lewisohn, 1954; Tanner, 1959) despite the early encouraging reports of the use of pyloroplasty alone (Horsley, 1926; Judd and Nagel, 1927). Secondly, there are those patients with the pseudo-ulcer syndrome. Barfred (1959) described a significant percentage of patients with duodenal ulcer symptoms, some with an irritable cap on barium studies, whom he considered not to have duodenal ulcer but rather functional pyloroduodenal irritability which could be likened to spastic colon. Many of his patients, in fact, had a high acid output and nearly one-third developed duodenal ulcers at a later date, so that a high proportion of patients in this subgroup could be expected to develop recurrent ulcer symptoms. One can only surmise that if any patients had an entirely functional disorder some might be improved and the remainder would continue to have symptoms of epigastric distress indistinguishable from a peptic ulcer syndrome. The subsequent satisfactory results from secondary vagotomy lends strength to the suggestion that at least some of these patients actually had a duodenal ulcer or preduodenal ulcer state. Thirdly, the possibility of undiagnosed, unrelated disease does exist despite a diligent search at operation, and symptoms due to this would persist after pyloroplasty.

Unfortunately it does not seem possible to preselect these patients on clinical grounds. Despite the obvious tendency of these patients as a group to have a less than typical pattern of pain, it is well established that all genuine duodenal ulcers do not provoke classic symptoms. Radiological signs will frequently confirm the diagnosis but up to 10 per cent of later proved duodenal ulcers will not be diagnosed b routine investigation. Thus, the few patients wit normal barium-meal examinations should not necessarily have been denied surgery. Minor changes suc as an irritable cap are just as likely as not to b associated with a duodenal ulcer (Templeton, 1965) whereas persistent deformities of the duodenal ca are found not to be due to duodenal ulcer disease i less than 5 per cent of cases (Bockus, 1963). Th patients with moderate or marked changes o barium-meal examination and no ulcer at operatio may have included these few exceptions. Alternatively the months between radiographic examination an operation may have allowed healing without noticeabl scarring.

Finally, a true peptic ulcer syndrome may develo after pyloroplasty owing to gastric ulceration. It ha recently been suggested that pyloroplasty may b ulcerogenic on the grounds of prolonged antral gastri release due to delayed gastric emptying of solid foo and antral neutralization with alkaline reflux (Lulu Lawson, and Dragstedt, 1971). Indeed, Woodward Eisenberg, and Dragstedt (1967) warn agains pyloroplasty alone for the treatment of gastric ulce and report 3 recurrences after such a procedure.

Although there is a temptation to regard pyloroplasty as a non-destructive operation there is accumulating evidence to the contrary. Animal experiment have shown that pyloroplasty results in altere contraction patterns of the antrum and the first par of the duodenum so that the two contract simultaneously, preventing a pressure gradient betwee them (Ludwick, Whiley, and Bass, 1969). There i also evidence of delayed emptying for semi-solid food after pyloroplasty alone in dogs but more rapi emptying with liquids (Lulu and others, 1971) Buckler (1967) found a tendency for a small group o patients to have delayed emptying of semi-solid foo after pyloroplasty. Aylett, Wastell, and Wise (1969 found rapid emptying of a liquid meal after vagotom and pyloroplasty which they believed to be due largel to the pyloroplasty. This has been shown to be du to an 'incontinent stomach' and to be dependent o posture (McKelvey, 1970). Thus the effects o pyloroplasty on gastric emptying are similar to thos of vagotomy and pyloroplasty. As the genera consensus holds that many of the post-cibal symptom are due to the rapid emptying of hyper-osmola liquid into the small intestine, it is not surprising t find these symptoms to be present to virtually th same extent after both pyloroplasty alone an complete vagotomy and pyloroplasty. The incidenc found in the present study closely resembles that fo combined large series of patients after vagotomy an pyloroplasty (Cox, Spencer, and Tinker, 1969). similar experience of dumping symptoms afte pyloroplasty alone has been recently reporte (Amdrup, Nielson, and Jensen, 1970).

It is not to be supposed that the vagotomy i without effect. Rapid emptying of hyperosmola glucose solution was found after vagotomy alone when compared with normal controls (Hall and Read 1970). Diarrhoea, which is undoubtedly a majo complication after vagotomy, appeared to be les severe when drainage was added (Pollock, 1952). I the same study there was a notable incidence o hypoglycaemia after vagotomy alone. There is als evidence that selective (gastric) vagotomy reduces the incidence of diarrhoea to a certain extent (Kennedy and Connell, 1970; Kronberg, Malmstrom, and Christiansen, 1970).

Withholding vagal section does not protect the patient from at least moderate post-cibal symptoms, as found in the group of patients presented here. More than one-third of patients can be expected to have recurrent ulcer symptoms. It is not possible to predict on clinical or radiological grounds which patients will do badly. We therefore recommend that all patients requiring surgery in whom a reasonable diagnosis of duodenal ulcer is made should have a definitive ulcer operation even if no ulcer is obvious at exploration, provided that careful laparotomy excludes other pathology. The wisdom of this advice can only be confirmed by a prospective clinical trial.

TREATMENT OF GASTRIC ULCER BY HIGHLY SELECTIVE VAGOTOMY WITHOUT A DRAINAGE PROCEDURE: AN INTERIM REPORT

BY D. JOHNSTON, C. S. HUMPHREY, R. B. SMITH, AND A. R. WILKINSON

UNIVERSITY DEPARTMENT OF SURGERY, THE GENERAL INFIRMARY, LEEDS

SUMMARY

Fourteen patients with gastric ulcer alone and 5 patients with combined gastric and duodenal ulceration have been treated by highly selective (parietal-cell) vagotomy without a drainage procedure (H.S.V.) in the past 3 years. Before operation no evidence of gastric stasis was found, clinically, radiologically, or during tests of gastric secretion. Spontaneous acid output was low. Acid output in response to a test meal of meat extract was also found to be low. There was no evidence that in the patients with gastric ulcer alone the ulcer was due to pyloric channel disease with excessive release of gastrin by the antrum.

Each gastric ulcer was proved by frozen-section examination to be benign at the time of operation. No problems with gastric stasis were encountered in the early postoperative period. The vagotomy was shown to be complete on insulin testing in each of the 17 patients tested.

Follow-up ranges from 1 month to 3 years. The clinical progress of the patients has been good, and none has symptoms suggestive of recurrent ulceration or of gastric retention. Barium-meal examination in 11 patients who were followed up for more than 9 months showed satisfactory gastric emptying, without recurrent ulceration. While the need for much longer follow-up is obvious, these preliminary results are encouraging. Further trial of H.S.V. for gastric ulcer, preferably in the form of a prospective, randomized comparison with Billroth-I gastrectomy, now seems desirable.

PROVIDED that his ulcer could be induced to heal and his stomach to empty satisfactorily, the patient with a gastric ulcer would probably be better off with his pylorus than without it; better with his whole stomach than bereft of half of it. Encouraged by our results with highly selective vagotomy for duodenal ulcer (Johnston and Wilkinson, 1970) we have treated 19 patients who had benign gastric ulcer without evidence of gastric stasis by highly selective vagotomy without a drainage procedure (H.S.V.). In this operation only the acid- and pepsin-secreting parts of the stomach are vagally denervated, the vagal nerve-supply to the antral 'pump' being carefully preserved (Amdrup and Jensen, 1970; Johnston and Wilkinson, 1970). The antrum, pylorus, and duodenum are left completely intact. Compared with Billroth-I gastrectomy, this operation should have a lower operative mortality, produce fewer side-effects such as dumping, and be followed by less weight-loss and anaemia in the long term.

PATIENTS AND METHODS

Patients.—Full details are given in *Table I.* Of the 19 patients, 16 were male and 3 were female. Many of the patients were underweight. Fourteen had gastric ulcer alone, and 5 had gastric ulceration with scarring of the duodenum. The duodenal ulcer appeared to be active in only 2 patients. Most of the patients with gastric ulcer alone had received full medical treatment, including carbenoxolone sodium, and were referred for surgery either because the ulcer had failed to heal or because it had recurred. One patient was operated on as an emergency for haematemesis. Thirteen of the ulcers were situated near the incisura angularis or more distally, 2 were in the middle of the lesser curvature, and 4 were in the upper third of the stomach. At the time of operation 15 of the 19 ulcers were found to be active and 4 had healed. Initially, for technical reasons, only a few selected patients with gastric ulcer were treated by H.S.V., but with increasing experience it was found possible to treat all patients in this way, and the last 14 patients form a consecutive series.

The possibility of ulcer cancer was excluded in each patient by the use of a combination of tests: barium-meal examination, fibrescopy, studies of acid output, and finally by excision of the ulcer with frozen-section examination by an experienced pathologist at the time of operation. Cancer was not found unexpectedly at frozen-section examination in any patient with gastric ulcer.

The possibility that the gastric ulcer had arisen as a result of gastric stasis was excluded by clinical methods, supplemented by the information obtained from barium-meal examination and by measurement of the volume of resting juice in the stomach at the start of preoperative tests of gastric secretion. At operation the absence of pyloroduodenal narrowing was confirmed in each patient by the passage of a finger or Hegar's dilators through the pylorus and proximal duodenum.

Tests of Gastric Secretion.—

1. *Spontaneous Acid Output (B.A.O.) and Maximal Acid Output (P.A.O.(PG)).*—Before operation spontaneous acid output (in 1 hour) and the response to intramuscular pentagastrin (Johnston and Jepson, 1967), in a dose of 6 μg. per kg. body-weight, were measured in 17 patients. The pentagastrin response was expressed as P.A.O.(PG) (output in the peak 20-minute period × 3, in mEq. per hour). Measurement of B.A.O. and P.A.O.(PG) was repeated 4–8 days after operation in each patient. The dose of pentagastrin used then was 10 μg. per kg. body-weight (Jepson, Lari, and Johnston, 1968).

2. *Response to Meat Extract (Oxo)* (Welbourn and Burns, 1964; Giles and Clark, 1966; Johnston, Humphrey, Smith, and Wilkinson, 1971).—This test was used as a measure of the activity of the gastric antrum. Gastrin release was stimulated by placing 100 ml. of Oxo solution at pH 7 and room temperature into the stomach via a nasogastric tube. Nine patients, all of whom had gastric ulcer alone, underwent this test before operation. Acid outpu expressed as P.A.O.(Oxo) (peak 20-minute output × 3, in mEq. per hour).

3. *Hollander Insulin Test* (Hollander, 1948).— test was performed 4–8 days after operation i patients and omitted in 2 on account of age and ca vascular disease. The dose of insulin used was o per kg. Venous blood-samples withdrawn 30 an minutes after the insulin injection established tha blood-glucose concentration had decreased to less 35 mg. per 100 ml. in each test. Acid output expressed as P.A.O.(I) (peak 30-minute output in mEq. per hour).

The methods used in these tests have been descr previously (Johnston and Jepson, 1967; Johnston Wilkinson, 1970; Johnston and others, 1 Titration was to the pH 7 end-point, but B.A.O. also expressed as 'free' acid, with titration to 3·5.

Clinical Result.—This was judged at the Ga Follow-up Clinic by a panel of observers who kept in ignorance of the preoperative diagnosis the type of operation which had been performed they had written down their collective assessme accordance with a modified Visick classifica (Visick, 1948). Visick grade 1 signifies a pe result; 2, near perfection with only trivial side-ef easily controlled by care; 4 means failure du recurrent ulceration or severe side-effects, whi signifies a satisfactory result with freedom from pain but somewhat marred by side-effects which not be entirely avoided. No formal assessment attempted in 8 patients who were followed up less than 9 months. Their clinical progress has satisfactory to date.

Barium-meal Examination.—This was ca out in 11 patients who had been followed up f least 9 months after operation.

Operative Technique.—The technique of H. for duodenal ulcer has been described previousl detail (Amdrup and Jensen, 1970; Johnston Wilkinson, 1970) (*Fig.* 1). The presence of a ga ulcer poses special problems: first, because the is usually close to the antral nerves (nerve Latarjet) which must be preserved, and, secon because the ulcer must be excised and submitte frozen-section examination to exclude the possib of malignancy. At first these factors deterred us f using H.S.V. in any except the occasional cas gastric ulcer, but with increasing experience we found it possible to treat all cases of gastric ulce this way. A transgastric approach to the ulcer vi appropriately sited gastrotomy incision is prefe (*Fig.* 2) because it is difficult to excise the ulcer f outside the stomach without damaging the nerve Latarjet. The entire ulcer, together with a dis surrounding mucosa, is excised with the diathe blade or scalpel. The fibrous base of the ulcer usually so thick that the stomach wall was perfor during this manœuvre in only 6 of the 19 ca Bleeding was controlled by deeply placed interru catgut sutures. The gastrotomy incision is m longitudinally and is placed, whenever possible the proximal three-quarters of the stomach whic to be vagally denervated. The incision is cl longitudinally. In the case of an ulcer that is dist the incisura the gastrotomy has to be made in

Cases 1–14 had gastric ulcer alone; *Cases* 15–19 had both gastric and duodenal ulcers. *Cases* 2–19 were treated by H.S.V. alone; *Case* 1 had a 70-g. segmental gastric resection in addition to H.S.V. *B*, Before operation. *A*, 5–9 days after operation.

antral region, on whose motility gastric emptying will depend. The incision should then be placed not in the middle of the anterior gastric wall but along the greater curvature, so that denervation of the inferior half of the anterior wall of the antrum may be avoided. Again the incision is closed longitudinally. Edge-to-edge apposition without inversion is the aim. Oedema and fibrosis around the ulcer often obliterate the normal plane of dissection between the lesser curvature of the stomach and the lesser omentum which contains the nerves to the antrum. This problem can be overcome by the use of a combined approach from the front and from the lesser sac after mobilization of the greater curvature, and by the ligation of tissues in continuity with transfixion sutures placed close to the wall of the stomach. A finger, or a Hegar's dilator, is passed through the pylorus into the second part of the duodenum and if the 'pyloric channel' does not admit the distal finger-joint or a 14-mm. dilator (Kirk, 1970) some degree of obstruction to the gastric outlet must be suspected. In these circumstances it might be advisable to resort to gastric resection or to a vagotomy with drainage procedure instead of H.S.V. Stenosis was found in only 1 of our patients and was treated by simple digital dilatation.

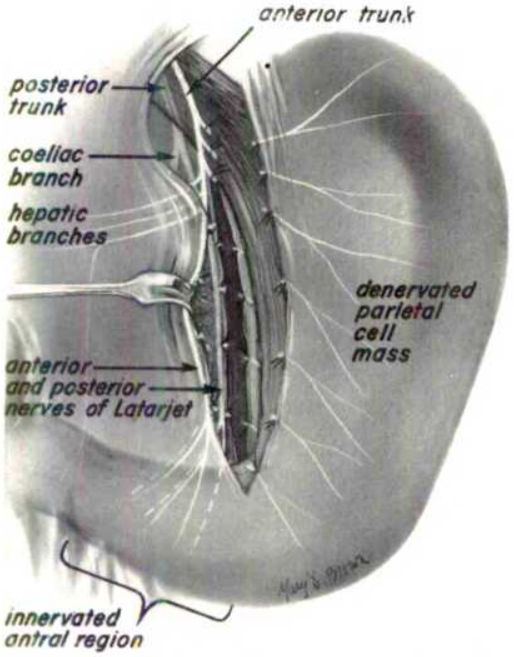

FIG. 1.—Highly selective vagotomy without a drainage procedure. The anterior and posterior vagal nerves of Latarjet to the antral region are preserved in addition to the hepatic and coeliac branches of the vagus. Some artistic licence has been used in order to depict the posterior nerve of Latarjet.

The length of prepyloric stomach left innervated ranged from 5 to 8 cm. Operating time varied from 60 to 150 minutes, with a mean of 110 minutes.

RESULTS

Clinical.—

In Hospital.—The patients' convalescence was without incident and none developed gastric retention. The mean length of stay in hospital after operation was 12 days.

Follow-up.—The patients have fared well since their discharge from hospital. Of the 11 who have been followed up for more than 9 months, 3 are classified as Visick grade 1, 6 as grade 2, and 2 as grade 3. The commonest side-effect is epigastric fullness after meals, which causes almost half the patients to restrict the size of their main meal to about two-thirds of what they ate formerly. Of the 2 patients classified as Visick grade 3, 1 has episodic diarrhoea of moderate severity, and the other experiences epigastric discomfort which is unlike the pain of his ulcer. None of the patients has experienced pain of ulcer type and none has symptoms suggestive of gastric stasis.

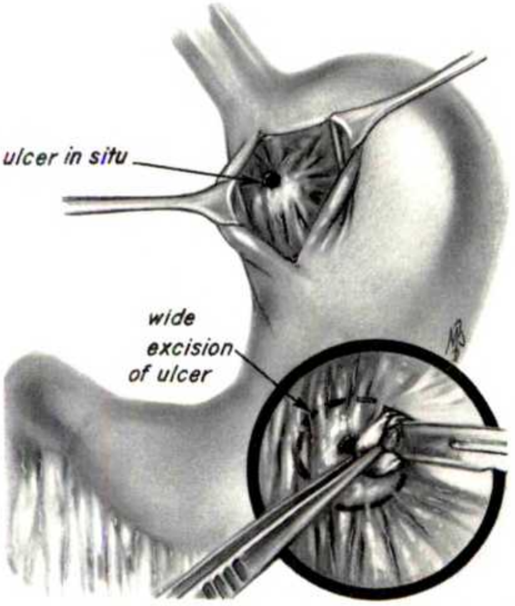

FIG. 2.—Malignancy is excluded by complete excision of the ulcer via a longitudinal gastrotomy followed by immediate frozen-section examination of the specimen.

Barium-meal Examination.—In the 11 patients who had been followed up for at least 9 months barium-meal examination revealed no sign of recurrent ulceration. The volume of resting juice in the stomach was not excessive and gastric emptying was satisfactory.

Gastric Secretion (*Table I*).—

1. *Response to Meat Extract before Operation.*—Mean peak acid output in response to Oxo solution (P.A.O. (Oxo)) was 5·6 mEq. per hour in the 9 patients who were tested. This was, on average, only 20 per cent of their P.A.O.(PG). There was no secretory response to the meat extract in 3 of the 9 patients. (These figures should be compared with the mean P.A.O. (Oxo) before operation in 26 patients with duodenal ulcer of 21·7 mEq. per hour, which was 47·8 per cent of their P.A.O. (PG).)

2. *Spontaneous Acid Output (B.A.O.).*—Only 2 patients were found to be still secreting 'free' acid after operation. B.A.O. (to *p*H 7) decreased from a

mean of 2·2 mEq. per hour before H.S.V. to 0·3 mEq. per hour after H.S.V. in 12 patients with gastric ulcer alone. The mean reduction was only 76 per cent, largely because there was little reduction in B.A.O. in 2 patients who were hyposecretors before operation.

3. *Response to Pentagastrin* (*P.A.O.(PG)*).—Mean P.A.O. (PG) in patients with gastric ulcer alone was 25·1 mEq. per hour before H.S.V. and 8·0 mEq. per hour after H.S.V., a mean reduction of 66 per cent. The mean reduction in 4 patients with combined gastric and duodenal ulcers was 57 per cent.

4. *Insulin Test.*—All 17 tests were negative, signifying that the vagotomies were complete. They were negative by Hollander's criteria and also by all other criteria since there was no response in any test.

DISCUSSION

It should be pointed out that the follow-up of our patients is very brief, only 9 patients having been followed up for more than 1 year and none for longer than 3 years. Hence no claims can be made for the effectiveness of H.S.V. in curing gastric ulcer in the long term. On the other hand, there is good evidence, both clinical and radiological, that gastric emptying is satisfactory, despite the absence of a drainage procedure. If gastric stasis has not become manifest within a year of operation it is unlikely to develop at a later date. Thus, one potential cause of recurrent gastric ulceration appears to be absent.

Truncal or selective vagotomy with a drainage procedure provides a cure in most cases of gastric ulcer (Dragstedt and Woodward, 1951; Hendry and Bahrani, 1965; Burge, 1966; Forrest, 1969; McNeill, McAdam, and Hutchison, 1969; Duthie, Moore, Bardsley, and Clark, 1970; De Miguel, 1970). The incidence of recurrence, however, is somewhat higher than that which follows Billroth-I gastrectomy. This achievement is all the more impressive when one considers that 20 per cent of the vagotomies are likely to have been incomplete (Fawcett, Johnston, and Duthie, 1969). Highly selective vagotomy (selective proximal vagotomy) *with a drainage procedure* also yields good long-term results in the surgical treatment of gastric ulcer (Holle and Hart, 1967). The results of the present study indicate that highly selective vagotomy *without a drainage procedure* (H.S.V.) gives good clinical results in the treatment of patients with benign gastric ulcer, at least in the short term. Particularly encouraging features were the complete relief from ulcer pain experienced by all the patients, and the absence of vomiting and of other symptoms of gastric stasis. The results of postoperative barium-meal examinations were satisfactory although it is recognized that the emptying of barium does not necessarily reflect the emptying of solid food. The results of the secretory tests were also satisfactory, with evidence of completeness of the parietal-cell vagotomy in each case, virtual abolition of spontaneous secretion of 'free' acid, and reduction of the peak response to pentagastrin (P.A.O. (PG)) by 66 per cent.

Certain important objections to the surgical approach which we have adopted will now be considered. It has been suggested, for example, that H.S.V. is illogical, if the Dragstedt (1956, 1971) theory of the aetiology of gastric ulceration is assumed to be correct, that it is dangerous, because of the risk that an ulcer cancer will be missed, and finally that the results of Billroth-I gastrectomy for gastric ulcer are so eminently satisfactory and so clearly better than those of vagotomy with a drainage procedure that any change in surgical management is quite unjustifiable. Let us examine each of these objections in turn.

According to Dragstedt (1956, 1971), gastric ulceration develops as a result of gastric stasis, excessive release of gastrin, and the resulting gastric hypersecretion. Certainly, it is true that anything which causes delayed gastric emptying, such as pyloric stenosis (Burge, 1966) or complete gastric vagotomy (Linares, de la Rosa, Woodward, and Dragstedt, 1964), is liable to lead to gastric ulceration. However, although stasis causes gastric ulceration it does not follow that the gastric ulcers which we see in clinical practice are caused by stasis. Studies of gastric emptying which were performed in patients with gastric ulcer by Buckler (1967) and Griffith, Owen, Campbell, and Shields (1968) suggest that gastric emptying of solid food is within normal limits in most patients with gastric ulcer, although a few individuals do have delayed emptying. In our own patients the following features led us to believe that gastric stasis was not the cause of their ulcer: they did not vomit copiously; they did not have a succussion splash; there was no delay in the emptying of barium before operation; when a nasogastric tube was passed the volume of the resting juice in the stomach was not excessive (less than 150 ml.), and food residues were not found. Spontaneous acid output was low/normal, suggesting that circulating gastrin levels were not unduly high, because the finding of maximal acid outputs within the normal range implied that the parietal cell mass was normal in size. The acid responses to a test meal of meat extract, far from being excessive, as might have been expected if the Dragstedt theory were correct, were in fact small—only 20 per cent of the maximal acid output and about one-quarter of the acid response to meat extract of patients with duodenal ulcer. At operation a finger was passed from the stomach into the second part of the duodenum in each patient. No sign of pyloric obstruction or of duodenal obstruction was found in any of the patients with gastric ulcer alone and only 1 of the 5 patients with combined gastric and duodenal ulcers was found to have pyloroduodenal stenosis (defined by Kirk (1970) as a pyloroduodenal channel which will not admit the distal interphalangeal joint of the index finger or a 14-mm. Hegar dilator).

As to the problem of ulcer cancer, clearly the treatment of a potentially curable lesion by a conservative operation is a tragic error. As many as 5–10 per cent of patients whose gastric ulcer appears to be benign on gross inspection have, in fact, an occult ulcer cancer (Forrest, 1969). If such cancers are treated by radical resection the prognosis is much better than that of gastric cancer in general (Runyeon and Hoerr, 1957; Brown, Cain, and Dockerty, 1961). While all this is beyond dispute, we think that the chances of an ulcer cancer being missed can be reduced to a minimum by the use of clinical methods supplemented by fibrescopic examination of the ulcer, with biopsy and cytological examination. An accuracy rate of 99·3 per cent in differentiating between benign and malignant ulcers of the stomach can be achieved by such means (Arnold, Hampton, Olin, Glass, and Carruth, 1960). Finally, at operation the surgeon has a further opportunity to inspect the ulcer directly and if he still harbours the slightest suspicion that the ulcer is malignant he should perform a gastrectomy. Even if the ulcer appears benign, it should always be exised *in toto*, or at the least its epithelial margin should be excised, and the specimen submitted to immediate frozen-section examination by an experienced pathologist. In our opinion the routine use of these measures will virtually eliminate the possibility that an early carcinoma will be treated in an inappropriate fashion.

It might well be asked what possible advantages H.S.V. could possess compared with the time-honoured Billroth-I gastrectomy for gastric ulcer, which yields good results in 80–90 per cent of patients and has a recurrent ulcer rate of 0–2 per cent (Swynnerton and Tanner, 1953; Duthie and others, 1970). We would answer that an operation which involves neither resection of one-half to two-thirds of the stomach nor an anastomosis is likely to be safer than one which does; statistically significantly safer, not within any individual surgeon's experience but in the global context of the treatment of many thousands of patients. We have now treated 170 patients with duodenal or gastric ulcer by H.S.V. without operative mortality and indeed without any major postoperative complication related to the operative procedure. Secondly, in the case of gastrectomy what is done cannot be undone. Many patients will develop iron-deficiency anaemia and a few will become thin, anaemic, osteoporotic 'gastric cripples'. Their lost stomach cannot be restored to them. Such sequelae should be rare after H.S.V., which preserves the entire gastric reservoir with its emptying still regulated by a normally innervated antropyloroduodenal segment. Dumping has been found to be significantly less common after H.S.V. than after vagotomy with a drainage procedure (Humphrey, Wilkinson, and Johnston, 1972), and will probably also prove to be less common than after gastrectomy. If the ulcer should recur after H.S.V. effective treatment is available in the form of a gastrectomy. Admittedly, Duthie and others (1970) have shown that a Billroth-I gastrectomy yields better results than truncal vagotomy and pyloroplasty in the treatment of benign gastric ulcer. H.S.V., however, is followed by significantly fewer side-effects, such as dumping and diarrhoea, than is vagotomy with drainage (Humphrey, Walker, Pulvertaft, Goligher, and Johnston, 1971; Humphrey and others, 1972) when used in the treatment of duodenal ulcer, and hence it may well prove superior to vagotomy and drainage in the treatment of gastric ulcer also.

In conclusion, it has been shown that patients with gastric ulcer can be treated successfully in the short term by an operation which entails neither gastric resection nor destruction or by-pass of the pylorus. The potential advantages of such a procedure are obvious but its use should probably be confined at present to centres in which complete physiological evaluation and prolonged clinical follow-up of the patients are assured. Longer follow-up of larger numbers of patients and controlled trials are needed to show whether the early promise of H.S.V. in the treatment of gastric ulcer will be fulfilled.

Acknowledgements.—We thank Professor J. C. Goligher for his generous help, encouragement, and advice. We are indebted to the physicians of the Leeds General Infirmary for referring patients. Professor Goligher, Dr. C. N. Pulvertaft, and Dr. B. E. Walker kindly permitted us to include data from the Gastric Follow-up Clinic. R. B. Smith is supported by a grant from the Board of Governors of the United Leeds Hospitals. We also thank our secretary, Miss Elaine Bartholomew.

Now, to simplify treatment of pseudomonas chest infections.

Pyopen infusion

the published papers, Pyopen's success rate chest infections is 65% even though the majority of e patients described had severe underlying pathology.

he best results have been achieved with a dosage f 20-30G. I.V. daily. Pyopen infusion makes this dosage mpler to administer by providing Pyopen in ready-to-use fusion bottles with diluent and transfer needles or the easier preparation of infusion solutions.

yopen is, of course, a penicillin, and has proved valuable patients with known renal impairment: in such cases, owever, dosage should be reduced.

dult dosage: 20-30G. I.V. daily.
patients with renal impairment dosage should be reduced.
ontra-indications: Penicillin hypersensitivity.
de-effects: As with other injectable penicillins. In rare cases spontaneous in and mucous membrane haemorrhages due to interference with normal otting mechanisms have been reported.

Pyopen

Further information is available on request.
Pyopen* (carbenicillin sodium B.P.) is a British product originated by
Beecham Research Laboratories, Brentford, England. *regd.

RADIOTOM 619

for surgical diathermy

The *RADIOTOM 619 is a universal electrosurgical apparatus designed to meet all the clinical requirements of general surgery and the special requirements of neurosurgery.

The RADIOTOM 619 can be placed on a trolley. The small dimensions and the low weight of the unit also make it possible to mount it in a ceiling column, build it into a wall or to use it on a wall bracket or a floor column.

Honvan fosfestrol

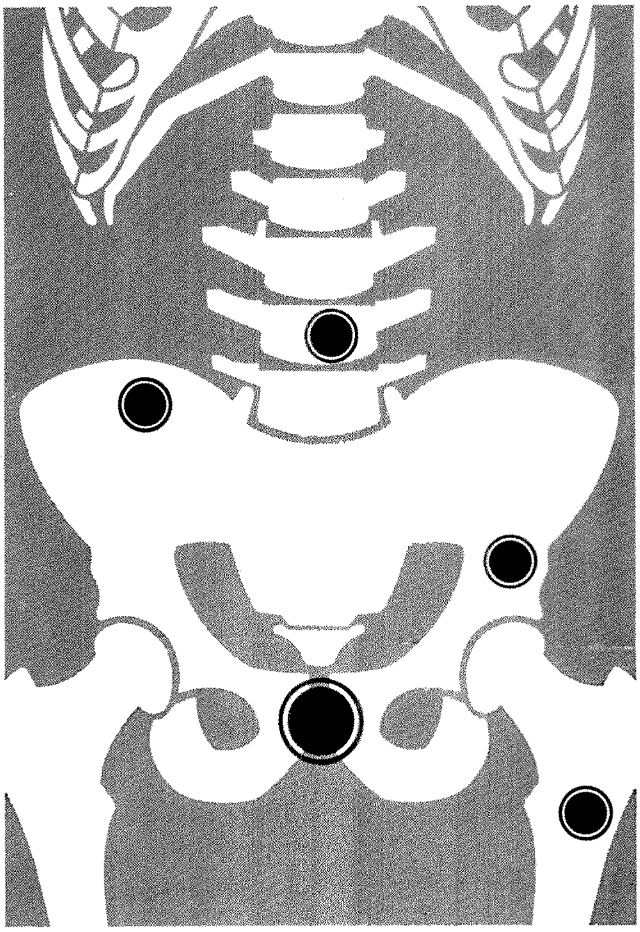
Honvan is pharmacologically inert until dephosphorylated. It is selectively activated by tissues rich in acid phosphatase, notably the prostate, where it exerts a local cytotoxic action.

Regression of prostatic tumours and metastases is observed in most patients, including a majority of those unresponsive to standard oestrogen therapy.

Response is rapid. **Honvan** is a practical alternative to surgery in acute urinary retention caused by prostatic carcinoma.

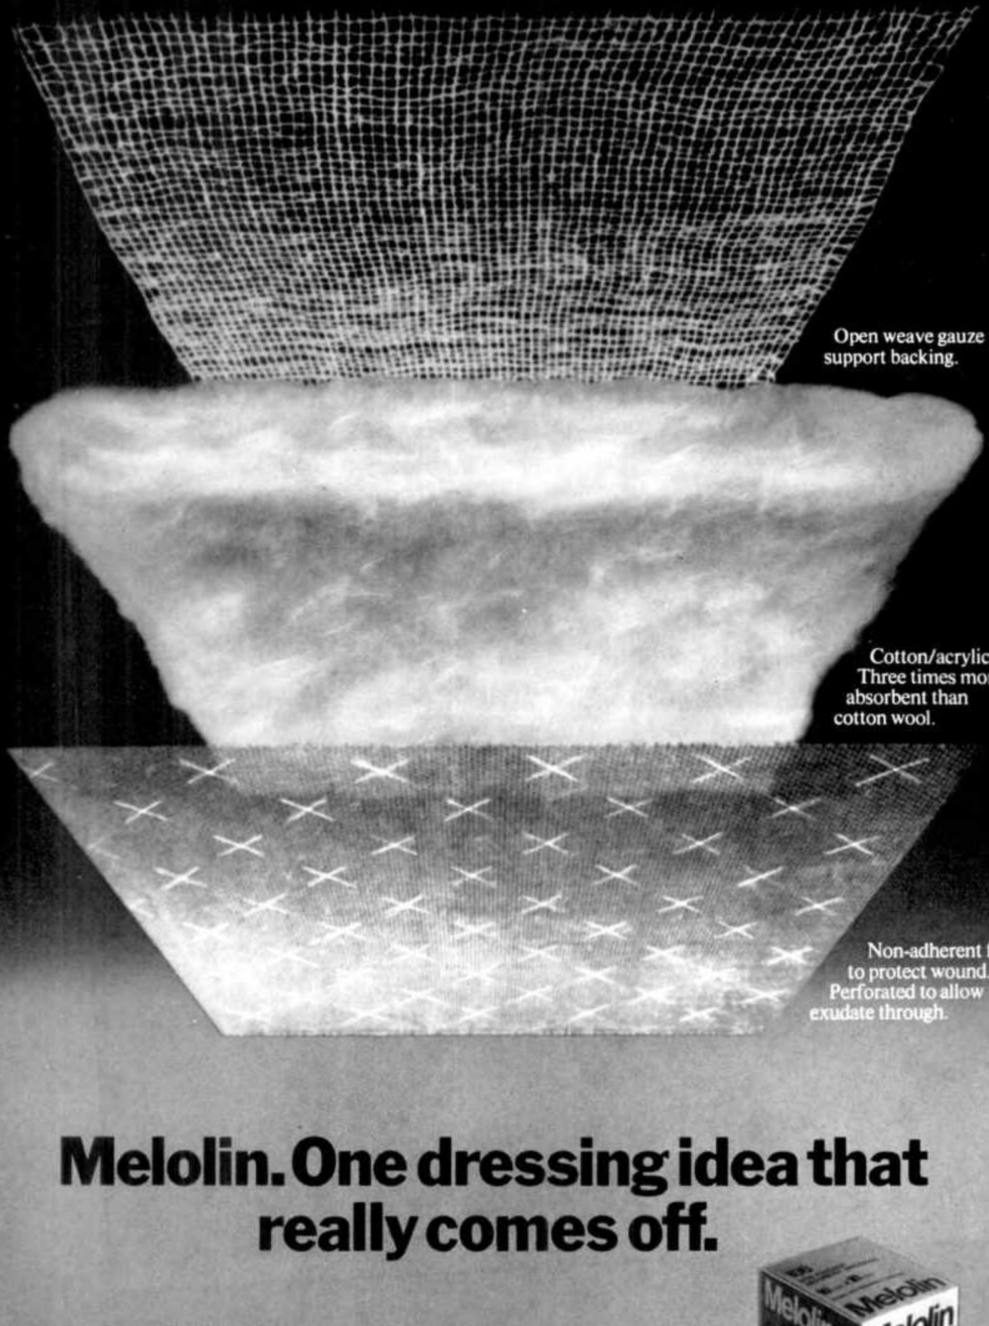
Gastric tolerance of **Honvan** is good and side effects comparatively rare.

Honvan is available for both intravenous and oral administration.



a selective cytotoxic action – in prostatic carcinoma

Full details are available on request from
WB Pharmaceuticals Limited.
A member of the Ward Blenkinsop Group,
Fulton House, Empire Way, Wembley, Middlesex.



Open weave gauze support backing.
Cotton/acrylic pad. Three times more absorbent than cotton wool.
Non-adherent film to protect wound. Perforated to allow exudate through.

Melolin. One dressing idea that really comes off.

Most dressings stick. And a pretty painful business it can be. But with Melolin the wound is protected by a non-adherent perforated film.

Exudate is taken through the perforations into an extra absorbent pad.

When you change the dressing it peels off. If you prefer, you can peel away the pad, leaving the film only on the wound.

Melolin comes individually wrapped (sterile) or in bulk.

Write for full information or ring Mrs E. Arthur, Welwyn Garden 25151.

Melolin is a registered trade mark of T. J. Smith & Nephew Limited.

Smith & Nephew Limited,
Bessemer Road,
Welwyn Garden City, Herts.

Prescribable on E.C. 10 as Perforated Film Absorbent Dressing (Drug Tariff).

Hospital medicine at its best.

THE VALUE OF UPPER GASTRO-INTESTINAL FIBRESCOPY

By IAN McCOLL
DEPARTMENT OF SURGERY, GUY'S HOSPITAL, LONDON

SUMMARY

In a series of 330 fibrescopies of the upper gastro-intestinal tract the most useful all-round instrument proved to be a long end-viewing panendoscope. The nature of the radiological errors revealed by endoscopy indicated that the latter is essential before embarking on surgery for antral gastric ulcers, radiographically negative dyspepsia, and further gastric surgery.

ONE of the most important advances in gastro-enterology in recent years has been the introduction of flexible fibrescopes which are much easier and safer to use than the rigid instruments and allow inspection and biopsy of every part of the oesophagus, stomach, and duodenum. The enthusiasm for these instruments has been universal, but Flavell's (1970) description of he fibrescope as 'expensive illuminated spaghetti' prompts the question of how much endoscopy really influences treatment. The present paper attempts to answer this question.

Table I.—TYPES OF FIBRESCOPES USED IN PRESENT SERIES

INSTRUMENT	FIELD	VIEW
Olympus panendoscope G.I.F. A.C.M.I. duodenoscope	Oesophagus Stomach Duodenal bulb	End
Olympus duodenoscope J.F.	Stomach Duodenum	Side
Olympus gastroscope G.F.B. and G.F.B.K.	Stomach only	Side
Olympus oesophagoscope E.F.	Oesophagus Upper stomach	End

MATERIALS AND METHODS

Six different fibrescopes were used in 330 examina-ions. Three were end viewing (Olympus panendo-cope G.I.F., Olympus oesophagoscope E.F., and the A.C.M.I. duodenoscope), and 3 were side viewing Olympus gastroscope G.F.B. and G.F.B.K. and duodenoscope J.F.). All these instruments allow a biopsy to be taken (*Table I*). The indications for ndoscopy are listed in *Table II*. Most of the patients had a barium-meal examination before endoscopy, as here is a risk of perforation of the oesophagus, specially with a side-viewing instrument, in the presence of an abnormality such as a pharyngeal pouch. Patients were examined if possible early in the morning after an 8-hour fast.

Metoclopramide hydrochloride, 20 mg. intra-muscularly, is given 1 hour before endoscopy if there is any likelihood of a full stomach, particularly following haematemesis. Atropine is given 30 minutes before to reduce bronchial secretions and to protect the heart rom vagal effects. A local anaesthetic lozenge is administered 15 minutes before and diazepam, 10–20 mg. intravenously, immediately before the examination. (Rather less than half the cases were conducted under a general anaesthetic with endotracheal intubation and muscle relaxants.) With the patient on his left side the instrument is gently advanced into the oropharynx. He is asked to swallow and although the patient often finds this difficult the attempt usually produces relaxation of the cricopharyngeus and allows the instrument to be passed into the oesophagus, the whole of which can be inspected with the end-viewing instrument, which permits suction rinsing of the lens, air insufflation, and biopsy. Provided that the instrument is advanced only when the way ahead is clear, perforation should be very rare. Fibre-oesophagoscopy is safe even in the presence of marked spinal deformities. The view obtained is incomparably better than that achieved by the rigid oesophagoscope and biopsy is a simple and safe affair. The long end-viewing duodenoscope provides a good view of the oesophagus, stomach, and duodenal bulb, but sometimes a side-viewing instrument is also required to see the antral roof, the fundus, and some aspects of the duodenal bulb and the medial wall of the second part of the duodenum.

Table II.—INDICATIONS FOR FIBRESCOPY IN 330 PATIENTS

Indication	*Percentage of Patients*
Oesophageal	18
Postoperative stomach	11
Haematemesis	8
Barium-negative dyspepsia	15
Additional clarification (duodenal and gastric ulcers and cancer)	48

Table III.—RADIOLOGICAL ERRORS

Lesion	*Percentage of Patients*	
Lesions missed		
Duodenal ulcer	10	36
Cancer	6	
Stomal ulcer	4	
Gastric ulcer	2	
Erosions, polyps	14	
Lesions erroneously reported		
Gastric ulcer	24	64
Duodenal ulcer	16	
Cardiac	14	
Stomal ulcer	10	

Radiology carried out within 3 weeks of fibrescopy.

RESULTS

The results were examined particularly in terms of their influence on treatment. Radiological errors occurred in 34 per cent of the patients (*Table III*), and these consisted of lesions which were seen endoscopically but missed radiologically, and lesions which were reported radiologically but could not be substantiated endoscopically or on subsequent follow-up. Of the radiological errors, 36 per cent were lesions which barium-meal examination had failed to detect.

Understandably the bulk of these consisted of small polyps, superficial erosions, and duodenal ulcers. The cancers were mainly small mucosal lesions, 2 of which could not be identified macroscopically in the excised specimen but which were clearly seen endoscopically and histologically. Of more practical significance were the lesions which had been detected radiologically but which did not actually exist. These comprised 64 per cent of the radiological errors, most of which had been diagnosed as antral gastric ulcers. A misleading radiological appearance was often explicable on endoscopy in terms of mucosal folds.

It is important to stress that the radiological reports were made by radiologists of very differing levels of experience, but when the radiographs were examined by expert gastro-intestinal radiologists who were ignorant of the endoscopic findings the number of errors was reduced by half.

An attempt was made to determine the influence of endoscopy on the treatment of patients (*Table IV*).

Table IV.—CHANGE IN TREATMENT AS A RESULT OF FIBRESCOPY

Change in Treatment	*Percentage of Patients*
Surgery avoided	17
Surgery precipitated	9
Total	26

In 26 per cent there was a change of treatment as a direct result of endoscopy, mainly in preventing unnecessary surgery (17 per cent). Most of these were patients who had been believed to have antral gastric ulcers. In 9 per cent surgery was precipitated by endoscopy, largely on the discovery of small cancers, gastric polyps, and duodenal ulcers. Those patients referred for endoscopy, however, constituted a selected group whose clinical problems had called for further investigation.

DISCUSSION

Endoscopy of the upper intestinal tract is complementary to barium-meal examinations. There is, o course, no question of competition between the tw methods but endoscopy is certainly helping th radiologist to define more precisely his areas c uncertainty. Although radiological errors occurred i 34 per cent of cases, this series does represent a selecte group of patients. In diagnosing oesophageal lesion there is little doubt that the fibre-oesophagoscope wi soon almost completely replace the rigid instrument In a series of 92 patients with barium-negative dyspepsia Cotton and Rosenberg (1971) reached a clinicall significant diagnosis in 34, including 2 cancers and 1 ulcers. As far as acute gastro-intestinal haemorrhag is concerned, endoscopy is proving of great value i that it can be carried out in the patient's bed in th ward under local anaesthesia with little inconvenienc In the series of Cotton and Rosenberg (1971) endoscop established a diagnosis in 86 per cent of the patien whereas radiology succeeded in only 38 per cent.

The radiology of the postoperative stomach notoriously difficult, particularly in the detection recurrent ulcers after pyloroplasty and in demo strating the presence of stomal ulceration. Radiolog is so unreliable that endoscopy is considered to b essential particularly before further surgery embarked upon. The most surprising finding in th present series was the large number of antral gastr ulcers which had been reported radiologically b which were not, in fact, present. In summary the findings would support the contention that fibrescop is essential before surgery is undertaken for antr gastric ulcers, further gastric surgery, and radi graphically negative dyspepsia.

THE IMPORTANCE OF BILE IN REFLUX OESOPHAGITIS AND THE SUCCESS IN ITS PREVENTION BY SURGICAL MEANS

BY E. W. GILLISON,
GENERAL HOSPITAL, NOTTINGHAM

K. KUSAKARI,
DEPARTMENT OF SURGERY, JIKEI UNIVERSITY, JAPAN

C. T. BOMBECK, AND L. M. NYHUS
DEPARTMENT OF SURGERY, ABRAHAM LINCOLN SCHOOL OF MEDICINE, UNIVERSITY OF ILLINOIS

SUMMARY

A study was instituted using the Rhesus monkey—an animal which has been found to resemble man both in respect of the anatomy of the gastro-oesophageal region and of the secretion of hydrochloric acid from the stomach—as a model.

Resection of the lower 2 cm. of the oesophagus a upper 1 cm. of the stomach produced reflux into oesophagus in all the monkeys. A bile-diversi procedure protected the monkeys from develop oesophagitis, while bile contamination of the gast juice caused oesophagitis of all grades with xception. Monkeys suffering from such oesophagitis were cured of their disease by Nissen valvulo-plasty even though the stomach was partially in the hest.

THE first record of reflux oesophagitis described as a linical condition was that by Quincke (1879), but it was not universally recognized as a common entity until the past two decades after the publication by Allison (1951). Since that time improved awareness of this disease has come about by better radiology, echniques of *p*H measurement and manometry, and more widespread endoscopy.

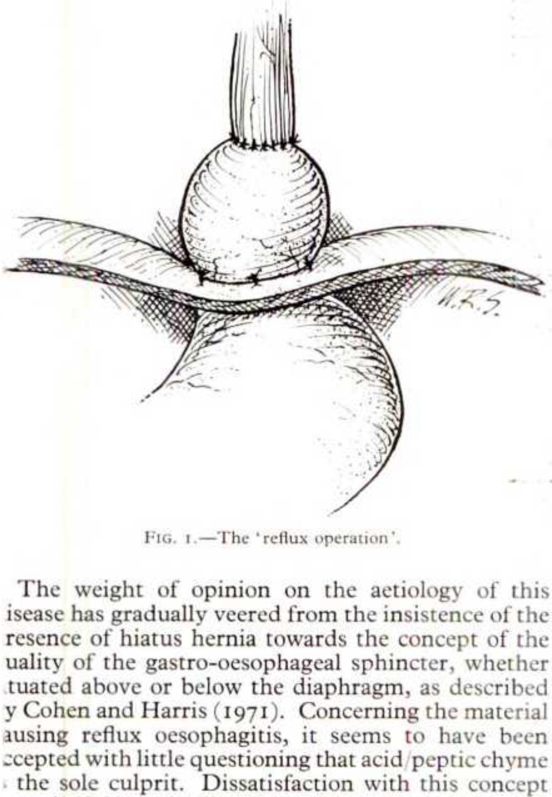

FIG. 1.—The 'reflux operation'.

The weight of opinion on the aetiology of this isease has gradually veered from the insistence of the resence of hiatus hernia towards the concept of the uality of the gastro-oesophageal sphincter, whether tuated above or below the diaphragm, as described y Cohen and Harris (1971). Concerning the material causing reflux oesophagitis, it seems to have been ccepted with little questioning that acid/peptic chyme the sole culprit. Dissatisfaction with this concept as arisen from the knowledge that oesophagitis is by o means rare after total gastrectomy nor in the presence of varying degrees of hypochlorhydria. urthermore, as most of the experimental work has been performed on non-primates it was thought that e Rhesus monkey (*Macacca mulatta*) would be more uitable for study because its maximal acid output and natomy of the oesophagus and stomach are so very lose to those of man.

MATERIALS AND METHOD

Twenty-nine monkeys were used for this experi-ment. Initially they were allocated to four groups y rota but later this was done by randomized election.

The normal monkey does not have radiological eflux demonstrable by barium when this is instilled nto the stomach. Twenty consecutive monkeys failed show reflux even under sedation when the stomach was distended with barium inserted through a naso-gastric tube. Resection of the lower 2 cm. of the oesophagus and upper 1 cm. of the stomach with an end-to-end anastomosis above the diaphragm (*Fig.* 1) caused reflux in 20 animals who were examined radiologically (*Fig.* 2). The above operation is henceforth described as the 'reflux operation'.

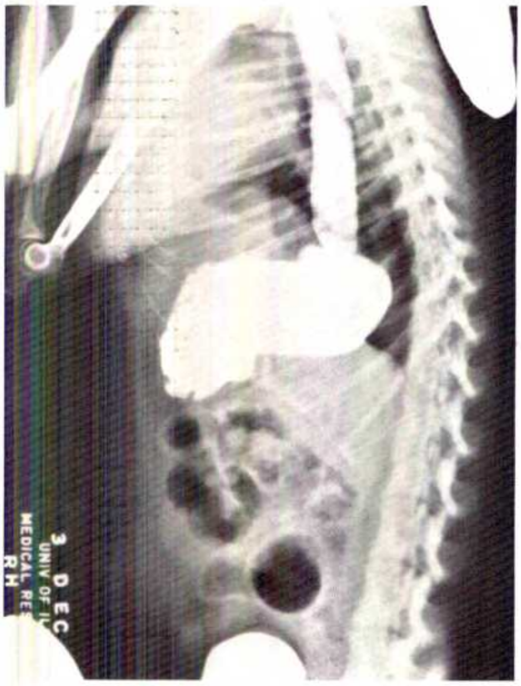

FIG. 2.—Reflux of instilled barium after the reflux operation.

Practical details of the operation are described elsewhere (Gillison, DeCastro, Nyhus, Kusakari, and Bombeck, 1972) but it should be mentioned that the vagal nerve-supply was preserved in every monkey.

Each group of monkeys was examined by an independent endoscopist at 1 and 3 months after undergoing the definitive surgery described below.

Group I.—Six monkeys had the reflux operation alone. They were studied so that the effect of the reflux of unaltered gastric juice could be seen.

Group II.—Seven monkeys had a Roux-en-Y type of diversion of duodenal juice after pylorectomy and closure of the duodenal stump. The open antrum was anastomosed to the efferent jejunum by a two-layered anastomosis (*Fig.* 3). Four weeks later the animals had the reflux operation performed through a left thoracotomy incision.

Group III.—Nine monkeys had a bile-contamination procedure performed (*Fig.* 4) before the reflux operation 4 weeks later. The common bile-duct was ligated to ensure adequate flow through the cystic duct and gall-bladder into the stomach.

Group IV.—Seven monkeys had a similar procedure to those in group III but in addition received daily depot histamine injections (2 mg. per kg.) after the cholecystogastrostomy.

The monkeys were sedated with phencyclidine hydrochloride (0·7 mg. per kg.) before endoscopy, which was done using a 7-mm. rigid bronchoscope by the endoscopist who was completely unaware of what previous surgery, if any, had been performed. His grading of oesophagitis is shown in *Table I.*

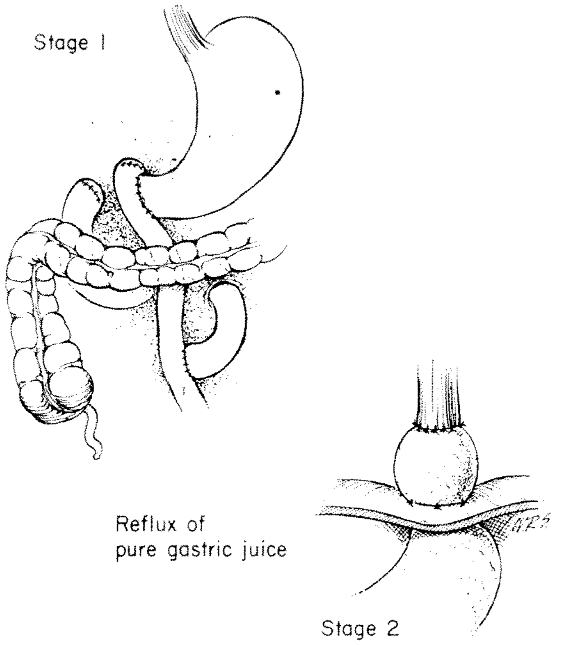

FIG. 3.—The bile-diversion operation carried out in animals in group II.

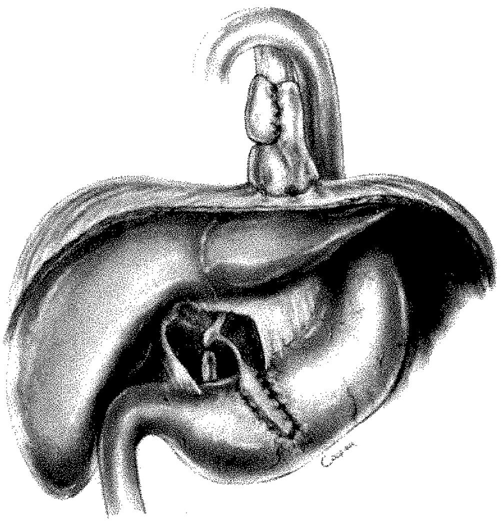

FIG. 5.—Intrathoracic Nissen valvuloplasty and the bile-contamination procedure.

Stricture was defined as a narrowing of the oesophagus as a result of oesophagitis which was sufficient to prevent the bronchoscope entering the lumen of the stomach.

Surgical prevention of oesophagitis was carried out in 5 monkeys with grade-2 oesophagitis. The left thoracotomy incision was reopened, the oesophagogastric junction was mobilized, and a Nissen (1970) fundoplication type of valvuloplasty was constructe (*Fig.* 5).

The progress of the monkeys was assessed by th endoscopist as before.

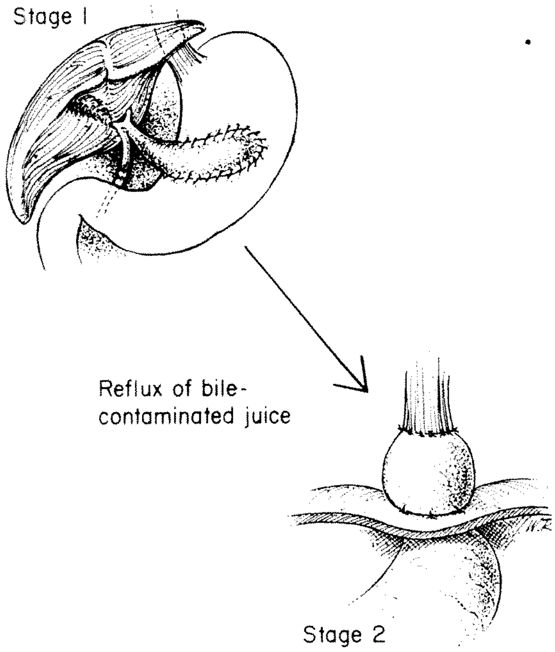

FIG. 4.—Bile-contamination procedure carried out in animals in groups III and IV.

554	2

RESULTS

The degrees of oesophagitis are summarized i *Tables II–V.* It can be seen that 23 out of the 2 monkeys studied survived for 3 months. The com monest cause of death was aspiration pneumonit which occurred in 4 monkeys. Some monkeys do n have an adequate cough reflex and this could well be the explanation of death due to aspiration pneumonitis. In group II, 2 monkeys died from a perforated stomal ulcer and a subphrenic abscess due to suture-line leakage.

Monkey	*Oesophagitis Grade*
598	2
600	2
667	1
700	3
335	3

Group I.—Two out of 6 animals had mild oesophagitis, not only at 3 months but for 6 months after the reflux operation.

Group II.—This group had bile-free gastric juices confirmed by aspiration studies. In the monkey which died as a result of a stomal ulcer, although the jejunum was perforated there was no coexisting oesophagitis. Only 1 of the 6 three-month survivors had oesophagitis, the remainder being normal despite continual reflux of pure acid/peptic chyme.

Group III.—Every animal in this group showed some degree of oesophagitis at all times. *Fig.* 6 shows a complete stricture in the monkey with grade 4 oesophagitis. Using a Wilcoxon (rank) statistical comparison, there was a significant difference between groups III and II ($P < 0.02$) in the degree of oesophagitis.

Group IV.—These animals were found to have a similar incidence of oesophagitis to that occurring in group III. One animal (No. 335) had developed a 'peptic ulcer' just 1 cm. above the gastro-oesophageal anastomosis. Thus, the addition of depot histamine failed to worsen the degree of oesophagitis.

Surgery for Reflux.—Endoscopy was possible 4 weeks after the Nissen (1970) fundoplication in 4 out of the 5 monkeys. The 4 survivors had no oesophagitis at endoscopy and the 1 which died had a lung abscess and grade 1 oesophagitis at post-mortem examination. Despite the valvuloplasty being in the chest it functioned as a barrier against noxious reflux.

DISCUSSION

A brief comment must be made concerning bile rather than pancreatic juice being chosen for mixing with chyme. Previous work by Gillison, Capper, Airth, Gibson, and Bradford (1969) using a radiological test implied that heartburn was associated with the reflux of duodenal juice into the stomach and oesophagus. This symptom, according to Bernstein and Baker (1958), was strongly associated with oesophagitis when using their acid-perfusion test. Lambert (1962) has shown that pancreatic juice has a vital role in the development of oesophagitis in rats, while Moffatt and Berkas (1965) have demonstrated that bile can cause oesophagitis at any pH between 2 and 12 in dogs. We considered that bile was the vital ingredient because of the fact that pancreatic enzymes are inactivated below pH 5. The common bile-duct was ligated in the animals in groups III and IV because the cystic duct has been found to be easily obliterated after cholecystogastrostomy in our experience. Diverting the bile entirely through the gall-bladder prevented this cystic duct obliteration.

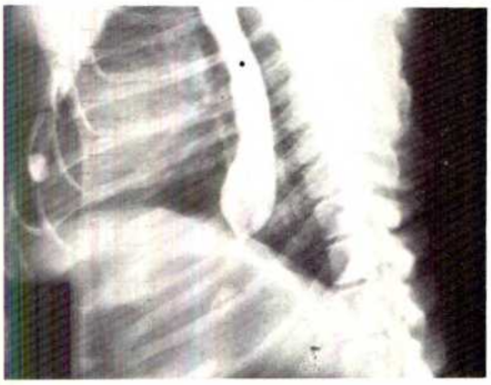

FIG. 6.—The oesophageal stricture in the animal in group III who died.

The monkeys in group IV were given daily injections of depot histamine because we wanted to mimic the state of hypersecretion of gastric juice such as that found in patients with duodenal ulceration. Our clinical experience is in keeping with that of Winkelstein (1935) and Wangensteen and Leven (1949), who found that duodenal ulceration was commonly associated with stricturing oesophagitis. However, despite the histamine we failed to produce a larger parietal cell mass, according to gastric secretion studies, and hence a more serious degree of oesophagitis did not occur in the monkeys in group IV.

Biliary oesophagitis is by no means a new idea owing to the work of Cross and Wangensteen (1951) as well as that of Moffatt and Berkas (1965). However, these workers used intestinal conduits to the oesophagus and preserved the lower oesophageal sphincter. Our experiment was different in two respects: the destruction of the sphincter and the mixing of bile with gastric chyme. These features meant that the mucosa of the oesophagus was exposed to the mixture of bile-contaminated chyme repeatedly over 3 months. To our knowledge, this is the first occasion that a 'peptic ulcer' of the oesophagus has been produced by experimental means.

Davenport (1968) described how bile could cause damage to the gastric mucosal barrier in a similar fashion to salicylates and alcohol. Bile was noted to cause more damage at a lower pH. Ferguson, Sanchez-Palomera, Sako, Clatworthy, Toon, and Wangensteen (1950) demonstrated how much more vulnerable the oesophageal mucosa is compared with other mucosae in the alimentary tract.

We do not refute the importance of acid chyme in reflux oesophagitis, but suggest that in man as well as in the monkey bile has a significant role in the genesis of the disease. The monkeys in group II correspond well with the 8 patients described by Holt and Large (1961), who cured reflux oesophagitis, caused by the long-abandoned cardioplasty operation for achalasia, using the Roux manœuvre.

The Nissen valvuloplasty is not the only way to prevent reflux but has the advantage of being easily performed above or below the diaphragm. The Hill posterior gastropexy is excellent at preventing herniation of the stomach through the diaphragm but, according to DeCastro, Nyhus, Gillison, Nakayoshi, and Bombeck (1971), this procedure does not protect the oesophagus against reflux. The Belsey Mark-IV valvuloplasty (Baue and Belsey, 1967) and the Collis (1968) operation are also effective barriers against reflux but require a thoracotomy for their execution.

THE CAUSE OF VARICOSITY IN SUPERFICIAL VEINS OF THE LOWER LIMB

BY W. G. FEGAN AND A. L. KLINE

THE CLINICAL RESEARCH DEPARTMENT, SIR PATRICK DUN'S HOSPITAL, DUBLIN

FOR many years surgeons have been aware of the paradox that some patients can have extremely bad varicose veins and no symptoms of venous insufficiency while other patients have severe symptoms and minimal varices.

We have also been aware that an increase in varicosity is not necessarily paralleled by an increase in symptomatology. In fact, many of us can recall cases of varicose veins of increasing severity over a lifetime in a patient who remained symptom-free. This anomaly has engaged our attention for many years. We have for some time been aware that dilated and tortuous veins in the thigh and sapheno-varices could disappear after treatment of incompetent perforators in the calf. This reversibility suggested to us that the primary defect was unlikely to be in the wall of the thigh vein as we had not in any way altered the wall of the proximal part of the vessel by treating the distal veins (Quill and Fegan, 1971).

We have often observed that when patients with tortuous long saphenous veins assumed the erect position a thrill could be detected by light palpation over the vein. This thrill lasted 15–20 seconds and disappeared when the superficial veins became filled. By clinical methods we were unable to tell whether this thrill was present during walking or if it varied with the rate of walking.

A palpable thrill is produced by vibration and being aware that vibration is one of the results of turbulence we became interested in investigating this phenc menon in more detail, particularly since we wer aware of the association between stenosis, turbu lence, and post-stenotic dilatation in the arteri system.

At present we are approaching this problem (1) b attempting to measure turbulence electronically an (2) by studying histological changes in the veins sites in which turbulence has been detected. We us a specially modified audiofrequency turbulence de tector (Gosling and King, 1969) which measure vibrations transmitted through the vein wall to th skin. At the same time we are doing frequenc analyses of the audio output of the Parks Model 8c Directional Doppler and comparing our tracings wit those found in experimental situations where tu bulence is known to occur. Using the turbulenc detector, we have been able to confirm our clinic findings in symptom-free patients with varicose lon saphenous veins when they assumed the erect positio Also, we have been able to show that turbulenc recommences with walking and synchronizes with th retrograde flow as indicated by the Parks Direction Doppler (*Fig.* 1). There is a reduction in the duratic and intensity of the turbulence with increase in spee of walking. In normal subjects neither retrograc flow down the long saphenous vein nor turbulen could be detected on assuming the erect position after commencing walking (*Fig.* 2). In the patien vith severe post-phlebitic symptoms and signs retrograde flow and turbulence were absent or, if present, vere much reduced when compared with asymptomaic patients (*Fig.* 3).

Turbulence, as detected by the methods described ere, appears to depend on high-velocity retrograde low, which can only occur if the calf pumps are unctioning effectively. In order for the blood to flow lown a dilated long saphenous vein blood in the listal part of the vein must first be drawn into the deep enous system. Clearance of blood into the deep veins nd thence proximally is reduced if the deep veins re blocked following previous thrombosis or if here is significant damage to valves in the deep or erforating veins. This probably explains why we ave been unable to detect turbulence in patients with evere calf-pump dysfunction.

If, as is possible, turbulence is the major factor in he development of prominent superficial varices, our indings help to explain the fact that prominent arices frequently occur in patients with good pumps nd, conversely, that prominent varices are relaively infrequent in patients with severe venous pump lysfunction.

The effects of turbulence on the vein wall have not et been elucidated. In vessels in which turbulence vas detected two histological changes were observed: 1) complete absence of muscle in the media at the art of the circumference closest to the skin (*Fig.* 4), .e., where vibration appeared to be maximal, and (2) hickening of the intima at the same point of the ircumference (*Fig.* 5). When flow in a vessel becomes turbulent there is a greatly increased shear force on the lining of the vessel and it is possible that the intimal thickening seen in veins is a result of this (*Fig.* 6). The effect of shear force is unlikely to be responsible for thinning of the muscle layer. We think that this may possibly be the result of vibration due to turbulence transmitted across the vein wall.

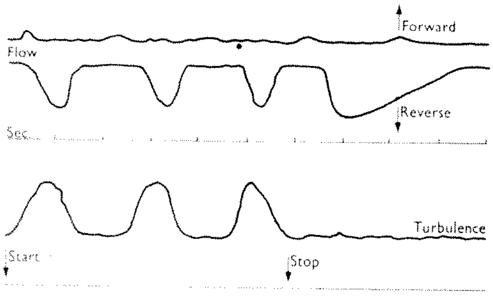

FIG. 1.—Turbulence is present and is synchronized with reverse flow in group I patients on walking.

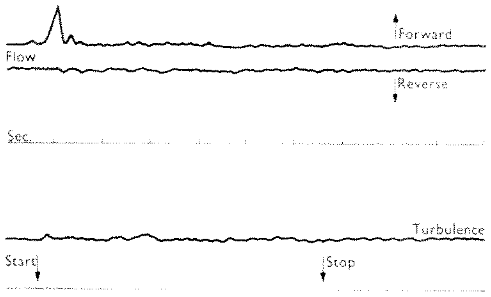

FIG. 2.—Turbulence is absent in normal subjects while walking.

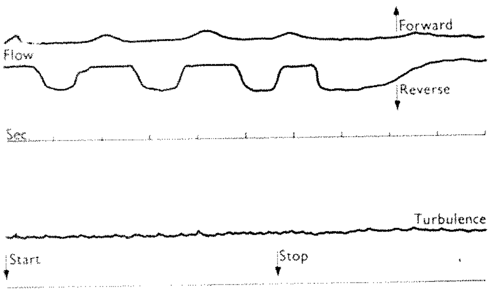

FIG. 3.—Turbulence and reverse flow are absent in group II patients while walking.

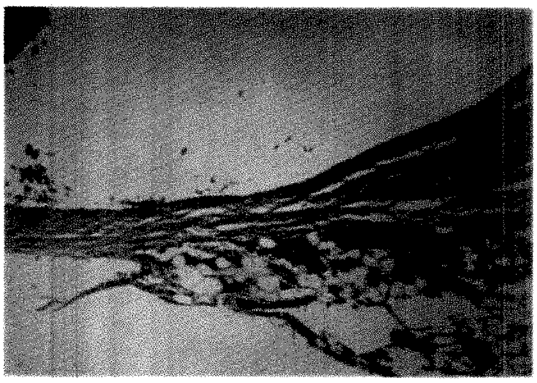

FIG. 4.—Histological section showing absence of muscle in the media at the point of the circumference closest to the skin.

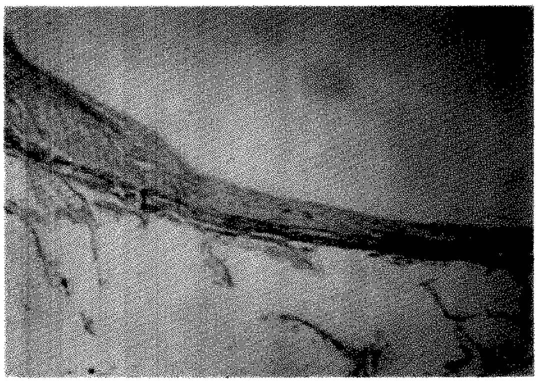

FIG. 5.—Histological section showing thickening of the intima in the media at the point of the circumference closest to the skin.

The understanding of this condition has been made difficult by the frequent superimposition of the effects of turbulent retrograde flow and pump dysfunction. To help to understand the aetiology and to clarify this condition for the sake of therapy it is necessary to divide the patients into three groups:—

Group I.—Those with prominent varices, no symptoms, and good calf pumps.

Group II.—Those with severe symptoms, few varices, and evidence of recanalized thrombosed deep veins with gross calf-pump dysfunction (post-phlebitic syndrome).

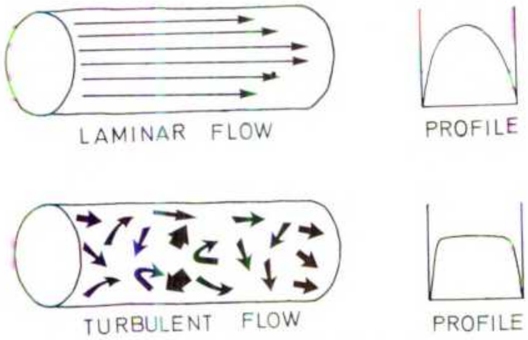

FIG. 6.—Flow profile with turbulence.

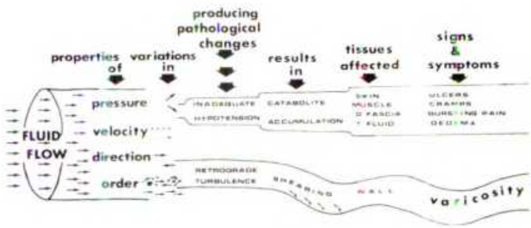
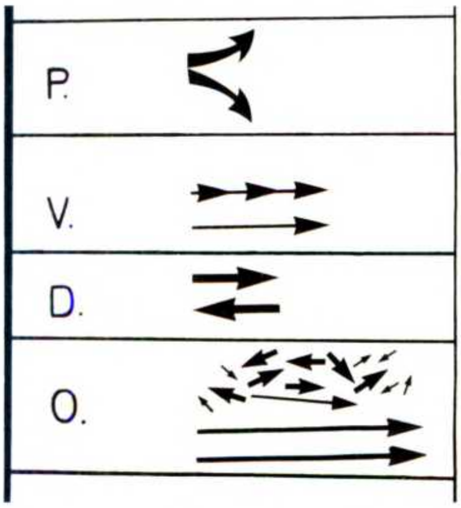


A



B

FIG. 7.—A, Properties governing flow in a closed system. Pressure: increased or decreased. Velocity: increased or decreased. Direction: forward or retrograde. Order: turbulent or laminar. B, Results of changes in flow patterns on the vein wall and surrounding tissues. P, Pressure. V, Velocity. D, Direction. O, Order.

Group III.—The sometimes confusing patients who have moderately severe varices and also evidence of calf-pump dysfunction.

A simple classification is given in *Table I*.

Table I.—CLASSIFICATION OF VARICOSITY IN SUPERFICIAL VEINS OF THE LOWER LIMBS

Group	*Description*
I	Varicose veins without symptoms are due to turbulence
II	Severe symptoms and minimal varices due to pump dysfunction
III	A combination of groups I and II

Young athletic males with large dilated long saphenous veins are typical of group I patients. Since they are usually asymptomatic, treatment is not always necessary. If one or two incompetent perforating veins can be detected in the calf or foot these should be occluded. A varying degree of regression of superficial proximal varices takes place. At least 3 months should elapse before considering flush ligation. We have found this to be necessary in only a small proportion of cases. We do not feel there is any indication for stripping these patients' veins. The only reason for providing treatment is to avoid the theoretical risk of thrombophlebitis in a dilated superficial vein following trauma.

Group II patients always require treatment, since the underlying pathology always develops from pump decompensation, whether due to damage to the valves in the deep or in perforating veins. Our treatment is to obliterate as many incompetent perforating veins as can be found. As yet there is no effective method of dealing with derangements of the deep venous system and, in our experience, occlusion of incompetent perforating veins usually results in a very considerable improvement in the limb, even in those patients in whom there is associated deep-vein damage (Henry, Fegan, and Pegum, 1971). All of these patients should be followed up because a minority require intermittent advice and additional treatment from time to time. Even in people with proximal pelvic occlusion the symptomatology is considerably improved (Fegan and Doporto, 1967). Some may have to continue to wear elastic stockings for support for the rest of their lives in order to control oedema.

The patients in group III have prominent varices and calf-pump dysfunction. In many, superficial varicose veins precede the development of signs and symptoms of calf-pump dysfunction. In our opinion in order to develop bad varicosity of superficial veins one must have good or adequately compensated pumps. The treatment of this group of patients is the same as that of the patients in group II, namely to seek out and to obliterate incompetent perforating veins. This is necessary to restore pump competence.

Signs and symptoms are evidence of decompensation of the pumps and not of leakage, which can often be completely masked by pump compensation. It is quite possible to have one or two incompetent perforating veins without any symptoms. At the moment we are observing closely a group of young patients in this category. The only effect so far of this incompetence is to give rise to ascending dilatation of superficial veins. At a critical point this dilatation leads to secondary incompetence of valves in the superficial system which is reversible after ambulatory hypotension is restored.

It is possible to attribute groups I and II to alterations in different basic properties governing flow in a closed system. As illustrated in *Fig*. 7, flow in an enclosed system can be either at high or low pressure forward or reverse, fast or slow, turbulent or laminar. When flow is retrograde and turbulent in the superficial system we get varicosity of that system, and then the pumps are unable to develop low pressure in the deep system. After the commencement of walking the tissues are unable to be adequately dialysed. This is due to the failure of the development of a favourable gradient necessary for tissue-fluid clearance. Failure to achieve this is the essential pathological feature of calf-pump dysfunction.

Acknowledgement.—We would like to express our appreciation to Mr. P. J. Byrne for technical assistance and for his considerable work in the development of the technique described in this paper.

SURGERY FOR CORONARY ARTERY DISEASE

BY D. C. BOUCH, D. J. JULIAN, A. H. KITCHIN, M. F. OLIVER, AND J. D. WADE

ROYAL INFIRMARY AND WESTERN GENERAL HOSPITAL, EDINBURGH

SUMMARY

Direct distal aortocoronary vein-grafts have been used in 20 patients suffering from ischaemic heart disease. In 16 patients the indication for surgery was severe angina pectoris failing to respond to medical measures. Seven patients had angina decubitus and were Class IV according to the New York Heart Association classification and 9 patients were in Class III. Two patients had recurrent myocardial infarctions and 2 were in cardiac failure. There were 14 good results, 2 failures, and 4 deaths. Post-mortem studies of the hearts confirmed the accuracy of selective angiography in identifying the sites of major coronary obstruction. Findings at surgery showed that the absence or presence of extensive peripheral disease beyond a block could not be reliably assessed in all cases. Histological studies of the veno-arterial anastomoses suggested that rigid atherosclerotic arterial disease is a cause of graft thrombosis and that endarterectomy is a useful procedure though its long-term value is uncertain.

DIRECT surgical by-pass grafts from the aorta to the coronary arteries beyond stenotic atherosclerotic lesions have been widely employed since Favaloro (1969) reported good results with the use of reversed saphenous grafts for ischaemic heart disease.

Johnson, Flemma, Harding, Cooper, and Lepley (1970) showed that the scope of surgery in the management of ischaemic heart disease could be greatly increased by utilizing peripheral grafts in vessels of 1–3 mm. diameter and that multiple grafts were usually required.

Twenty consecutively treated patients suffering from severe ischaemic heart disease have been subjected to direct revascularization in the Thoracic Unit at Edinburgh and the survivors have been clinically assessed during their subsequent course.

PATIENTS SELECTED FOR SURGERY

The majority of the patients suffered from severe incapacitating angina and were classified in Class III or IV according to the functional classification of the New York Heart Association. Class III patients had anginal pain on less than ordinary exertion and Class IV patients had cardiac insufficiency or anginal pain at rest. These patients had failed to obtain relief from the standard drugs, namely nitroglycerin and β-receptor blocking agents. There were also 2 patients who suffered from disabling recurrent attacks of myocardial ischaemia requiring repeated hospitalization and 2 who had gross cardiac failure associated with a ventricular septal defect in 1 patient and severe left ventricular akinesia in the other. These features are summarized in *Tables I and II.*

Table I.—DETAILS OF THE PATIENTS SELECTED FOR SURGERY

INDICATIONS	FUNCTIONAL CLASSIFICATION	NO. OF PATIENTS
Severe angina	III	9
Angina decubitus	IV	7
Recurrent infarction	I	2
Cardiac failure and ventricular septal defect	IV	1
Cardiac failure and akinesia of left ventricle	IV	1

Coronary angiography and left ventriculography were done in all the patients and formed the most important guide to selection for surgery and to the site and number of grafts required.

Sixteen patients had complete obstruction of two main coronary arteries and this was often associated with stenotic areas in the remaining artery jeopardizing the collateral circulation. Two had severe stenosis of one main artery. The 2 patients suffering from recurrent infarctions had total obstruction of the main circumflex or the branches of this vessel.

Left ventricular function was assessed by ventriculography and 15 patients had good contractility. Two patients had severe localized akinesia and 2 had poor general contractility in the distal two-thirds of the left ventricle, whilst 1 patient had almost total

akinesia of the left ventricle which was wrongly believed to be a left ventricular aneurysm.

There were 18 men and 2 women aged between 32 and 70 years with a mean age of 50. Sixteen patients had had one or more proved myocardial infarctions. Angina pectoris had been present for over 3 years in the 16 patients presenting with this symptom and it had been present for 5 years or more in 9 of these patients. Two patients were under treatment for hypertension.

The resting electrocardiogram was normal in 3 patients. Seven had pathological Q waves indicating previous myocardial infarction, while 10 others had ST-/ and/or T-wave changes of ischaemia or infarction.

OPERATIVE PROCEDURES

Eleven patients had single grafts and 9 patients had double grafts the details of which are shown in *Table III*. In 9 cases the internal mammary artery was implanted into ischaemic areas of the left ventricle using a modified Vineberg technique. This was usually done into the area of supply of the circumflex artery when diffuse disease of this artery unsuitable for grafting was present. The heart action was supported by cardiopulmonary by-pass during the operation, and a quiet operative field for the distal saphenous vein to coronary artery anastomosis was obtained by the use of moderate hypothermia, ventricular fibrillation, and venting of the left ventricle. Periods of aortic clamping varying from 6 to 36 minutes were used to obtain a bloodless field for accurate anastomosis and to avoid the need for dissection of the tissues surrounding the arteries. Fine 000000 monofilament interrupted sutures with double-ended needles were used.

Table III.—THE SITE AND TYPE OF VEIN-GRAFT EMPLOYED

SITE OF GRAFTS	NO. OF PATIENTS	WITH IMPLANT
Single grafts		
Aorta to right coronary artery	2	1

Table IV.—THE SITE OF ENDARTERECTOMY

SITE OF VEIN-GRAFT	NO. OF VEIN-GRAFTS	ENDARTERECTOMY	
		Proximal	Proximal and Distal
Right coronary artery	11	3	3
Left coronary artery	18	3	3
Total	29	6	6

As shown in *Table IV* there were 29 distal vein-grafts employed for 20 patients; proximal endarterectomy was done on 6 occasions with the object of obtaining a free flow of blood from above in the case of short obstructions, improving retrograde flow into proximal unobstructed myocardial arteries, and, more frequently, attaining a pliable unobstructed vessel at the site of anastomosis. Distal endarterectomy was done on 6 occasions usually in association with proximal endarterectomy of small extent for the reasons mentioned. Obstructing pieces of collagenous atherosclerostic material which were cylindrical in shape and up to 4 cm. in length were removed from the distal vessels and their branches where a plane of cleavage could be developed.

Distal endarterectomy from the right coronary artery in its lower third close to the crux extending into the posterior interventricular and right postero-lateral ventricular arteries was done in 3 cases, and from the left anterior descending artery, the diagonal artery, and the circumflex artery on 3 other occasions.

Recently the use of extensive blunt dissection and of a wide incision into the artery at endarterectomy has been avoided by employing carbon-dioxide-gas endarterectomy in the plane of cleavage. This modification was developed by Kuypers (1971) and reported by Vonk, Plum, and Geraedts (1967). It eliminates the use of needle injection of gas as originally described by Sawyer, Kaplitt, and Sobel (1967). There were 2 patients in whom grafts could not be placed at one of the expected sites owing to failure to find a vessel of suitable size, and 1 failure to disobliterate an extensively obstructed right posterior interventricular artery in a patient who died within 72 hours of surgery.

RESULTS

The subjective results of these operations for the relief of pain have been good in that 11 out of 13 survivors operated on primarily for angina pectoris of severe degree have been relieved of pain and have returned to a more active life than before surgery.

Four patients who had extensive distal endarterectomy are amongst those completely relieved of pain at rest and on exertion; in 1 of these the only graft achieved was at the site of endarterectomy.

In 1 patient pain recurred immediately after operation and has persisted since; there is angiographic evidence to suggest that the graft to the left anterior descending artery, which had an extensive distal endarterectomy, is closed; the left circumflex was unsuitable for a by-pass graft so that an internal mammary implant was done without apparent benefit.

One other patient still has cardiac failure and although the pain has been much less it has not been completely relieved.

In 2 patients postoperative selective angiograms to the origin of the graft in the aortic root have shown graft patency at 2 months and 6 months respectively. The 2 patients who had had recurrent infarcts and episodes of severe pain necessitating frequent hospital admissions preoperatively have been improved, but the follow-up period is only 6 and 8 months respectively.

A 70-year-old man in severe cardiac failure with a ventricular septal defect due to a myocardial infarct 3 months preoperatively is well, free of angina, and requires no diuretics in spite of partial recurrence of the septal defect after surgery. There has been no late mortality in those patients surviving the immediate postoperative period in a follow-up of 4–16 months and no serious postoperative complications. There have been 4 early postoperative deaths details, of which are shown in *Table V*.

Two deaths occurred within the 72 hours after surgery from cardiac causes.

Table V.—DETAILS OF THE 4 PATIENTS WHO DIED

PATIENT	AGE AND SEX	INDICATION FOR SURGERY	FUNCTIONAL CLASSIFICATION	LEFT VENTRICULAR FUNCTION	CAUSE OF DEATH	GRAFT PATENCY
R. C.	51 M.	Angina decubitus	IV	Good	Occlusive thrombus	Open
I. M.	49 F.	Cardiac failure	IV	Almost total akinesia	Low cardiac output	Closed
A. H.	60 M.	Angina decubitus	IV	Akinetic distal one-third	Septicaemia with right apical empyema	One open
W. P.	68 M.	Angina decubitus	IV	Akinetic distal one-third	Pulmonary infection	Open

The first patient (R. C.) developed severe retrosternal pain due to recent obstruction of the coronary artery which was totally blocked beyond the first 2 cm. by extensive atherosclerosis. At autopsy all the main coronary arteries were severely narrowed although there was a patent graft into the diseased anterior descending artery.

The second patient (I. M.) died after a long period of hypotension due to low cardiac output with repeated episodes of ventricular fibrillation. At autopsy there was extensive replacement fibrosis in the lateral and anterior walls of the left ventricle presumably from old infarcts. All the branches of the coronary arteries were severely and irregularly narrowed by atherosclerosis and recanalized totally occlusive lesions were identified in the anterior descending and circumflex arteries. The distal anastomosis of each graft was virtually completely closed by the spring-like action of the rigid thickened walls of the diseased arteries.

The 2 other deaths occurred 14 days after surgery which was complicated in 1 patient (A. H.) by intra-abdominal haemorrhage.

At autopsy in patient A. H. severe and ulcerated atherosclerosis was widespread, affecting the aorta and all the major arteries. An atheromatous abdominal aortic aneurysm was present.

Two aorta–coronary artery saphenous vein-grafts were present, the distal anastomoses being fashioned to the left anterior descending and right coronary arteries respectively.

Examination of the myocardium showed extensive areas of hyaline fibrous tissue replacing the myocardium in the inferior wall and extending into the lateral wall. In the inferior wall the myocardial fibres showed some atrophy and there was an increase in the amount of interstitial fibrous tissue.

All the branches of the coronary arteries were severely narrowed by atherosclerosis. Organized mural lesions were present in the circumflex artery.

VEIN-GRAFTS.—The left coronary graft was patent but showed a small amount of mural thrombus related to the sutures of the distal anastomosis. It was also noted that one of these sutures had passed through and had fragmented an atheromatous plaque. The right coronary graft was completely occluded by a mixture of recent thrombus and blood-clot. Typical laminated thrombus was identified in relation to the distal anastomosis which was itself almost completely closed off by the spring-like action of the rigid artery wall. It was interesting that no thrombus was identified in the right coronary artery lumen.

A left subphrenic collection of altered blood was found.

Death was the result of septicaemia complicating a right apical empyema.

At autopsy patient W. P. had a single patent aorta–right-coronary artery saphenous vein-graft; the left internal mammary artery had been mobilized and embedded into the substance of the anterior wall of the left ventricle towards the apex.

The myocardium showed much fibrous tissue in the inferolateral wall of the left ventricle and also in the anterior wall at the apex. In addition, focal ischaemic damage approximately 10–14 days old was noted in the inferolateral wall of the left ventricle.

Localized endarterectomy had been performed in the major coronary arteries which in many instances had left only a relatively small amount of supporting tissue, consisting of the adventitia and small fragments of media. Elsewhere the vessels showed severe irregular narrowing by atherosclerosis. The right coronary artery at a point just proximal to the vein-graft anastomosis was almost completely occluded by two entirely separate portions of recent thrombus. One portion of thrombus was formed on superficially eroded atheromatous plaques, whilst the other formed part of a large piece of mural thrombus related to the anastomotic line between the vein and the coronary artery at a point where the arterial wall was necrotic and thinned following the endarterectomy and suturing. The thrombus, although extensive and almost completely occluding the termination of the proximal part of the right coronary artery, did not significantly encroach upon the lumen of the vein or the distal parts of the right coronary artery.

The vein-graft was otherwise healthy and the internal mammary artery implant showed no abnormality.

The lungs showed chronic airways' disease and were congested with early bronchopneumonia. The airways were plugged with viscid mucopurulent material. A focal mild acute pancreatitis was present.

Death was thought to be primarily the result of respiratory failure.

The 4 deaths occurred in patients who had particularly severe degrees of widespread coronary atherosclerosis and in 3 cases poor left ventricular function. In 1 patient (I. M.) it was mistakenly thought that an aneurysm was present. This patient would not have been subjected to surgery if the left ventricular angiogram had been correctly assessed. It is well-recognized error. In 2 of these patients it was impossible to carry out the projected double vein-graft and only one was accomplished.

DISCUSSION

Though the incidence of asymptomatic ischaemic heart disease in people over the age of 40 is high, patients only present for investigation as the result of the development of stable or unstable angina or myocardial infarction. Unfortunately, unheralded sudden death is not uncommon but it is possible that minor premonitory episodes of unstable angina are often missed. Unstable angina is defined as the onset of fresh angina or the exacerbation of pre-existing angina and it is believed that the prognosis in such patients is much worse than that of stable angina which only carries an average death-rate of 4 per cent during the 5 years following its onset (Weinblatt, Frank, Shapiro, and Sager, 1968).

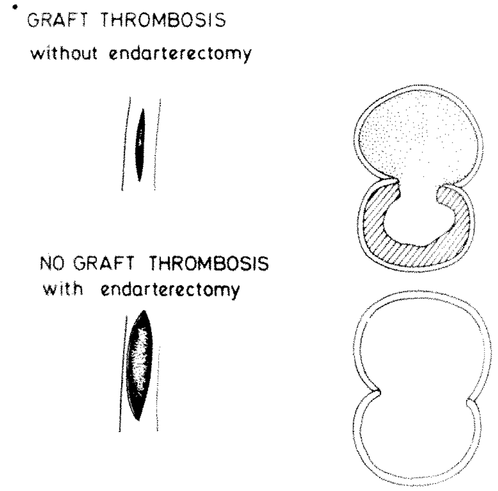

FIG. 1.—Diagrams showing the effect of using endarterectomy at the site of an anastomosis.

Angina in the patient who has had a myocardial infarct carries a death-rate of 8 per cent (Block, Crumpacker, Dry, and Gage, 1952), and in the future, with increasing knowledge, it will be possible to select for surgery patients who are at particular risk. At the present time there is insufficient evidence available to decide whether the mortality of this disease can be reduced by revascularization, though a long-term controlled study is being planned. The majority of the patients in the present series were treated on account of crippling angina and had been in functional Class III or IV with severe triple artery disease; this group is known to carry a higher mortality than the overall mortality for surgically treated patients reported from many centres (Morris, Reul, Howell, Crawford, Chapman, Beazley, Winters, Peterson, and Lewis, 1971).

At autopsy the coronary arteries were dissected from the heart and examined in longitudinal sections according to the method described by Bouch and Montgomery (1970). It was shown that conclusions based on the preoperative coronary angiograms were accurate in respect to the major sites and severity of the stenotic lesions in the major arteries, but were not accurate in indicating the presence of rigid mural atherosclerosis and obstructing lesions in the peripheral vessels.

The pathological evidence on the four hearts studied postoperatively suggests that there are advantages and disadvantages in endarterectomy.

In the absence of endarterectomy the rigidity of the diseased arterial wall may cause spring-like closure of the anastomosis (*Fig.* 1). This was seen in 3 cases and the fact that it was associated with distal vein thrombosis with absence of thrombus in the artery supports this hypothesis.

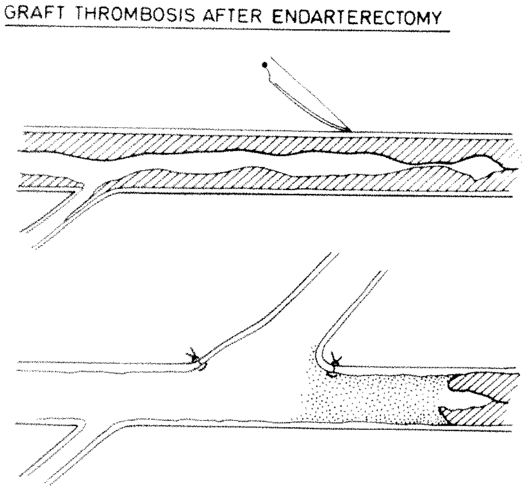

FIG. 2.—Diagrams showing graft thrombosis after endarterectomy.

On the other hand, damage by separation of atherosclerosis at surgery may provide a site for the origin of thrombus formation (*Fig.* 2).

One of the main advantages of placing the saphenous vein by-pass graft distally is that a healthy arterial wall is frequently found beyond the proximal severe disease in the coronary arteries. Unfortunately, in severe long-standing disease the peripheral vessels are often involved as well and coronary angiography has not proved an accurate guide to the presence of a patent healthy vessel beyond a major obstruction. Vonk and others (1971) have pointed out that it is difficult to distinguish between the so-called 'disuse atrophy' beyond complete obstruction and the presence of organic disease. It is impossible to avoid exploration of diseased vessels at surgery, and endarterectomy has been used on these occasions to permit direct revascularization although its long-term value is uncertain.

The value of internal mammary implantation is felt to be doubtful in comparison with direct coronary surgery, so that with increasing experience of multiple vein-grafts and endarterectomy its use should be limited to special cases; the extra operating time and blood-loss involved in adding this procedure to cardiopulmonary by-pass are additional disadvantages.

SYMPOSIUM ON CROHN'S DISEASE

THE VALUE FOR DIAGNOSIS AND RESEARCH OF SPECIAL INVESTIGATION ON RECTAL BIOPSIES IN CROHN'S DISEASE

BY I. M. P. DAWSON
PROFESSOR OF EXPERIMENTAL PATHOLOGY, WESTMINSTER MEDICAL SCHOOL, LONDON

SUMMARY

Proper processing and intelligent use of rectal biopsies and resected material from patients with Crohn's disease allow a wide range of histochemical and immunological, diagnostic and research procedures. Studies of enzyme distribution in biopsies have not fulfilled their early promise, and electron microscopy has not so far proved to be of great value in differential diagnosis. Techniques for determining mucosubstances, however, can be of considerable value in separating Crohn's disease from other conditions. Studies on the distribution of lymphocytes and plasma cells using selective antibodies to human immunoglobulins are practicable and likely to be of value. Close co-operation between the surgeon and the pathologist is essential.

WHENEVER tissues are surgically removed from a patient the surgeon and the pathologist have a dual responsibility. First, an accurate diagnosis, differential diagnosis, and, if possible, a prognosis must be given, and, secondly, any studies on the tissues which may add to the knowledge of the aetiology and pathogenesis of the particular disease diagnosed ought to be undertaken. Resected specimens normally provide ample material for both purposes. Small biopsies are intended primarily for diagnosis, which may be extremely difficult, and research must be subsidiary to this. It is, however, surprising how much additional valuable diagnostic information and research potential there can be in a small biopsy which has been properly preserved and handled because the surgeon and pathologist have discussed the patient together *before* the biopsy was taken. This paper considers the value and scope of special investigations for diagnosis, differential diagnosis, and research on biopsies and surgically resected specimens from patients diagnosed as actually or potentially suffering from Crohn's disease.

THE INITIAL HANDLING OF SPECIMENS

Resected Specimens.—Most unsuccessful histochemical and immunological investigations fail because the material was imperfectly handled when resected. The surgeon should let the pathologist know when resection is being undertaken and the pathologist should, whenever possible, collect the unfixed specimen himself, open it, demonstrate it to the surgeon if he wishes to see it, photograph it himself if facilities exist, and select blocks for appropriate processing immediately. Most specimens can subsequently be photographed satisfactorily if block-taking is carefully done. Appreciable delays before processing interfere not only with the histochemistry but also with the highest quality of histology on which differential diagnosis may depend.

Biopsies.—When a single indivisible piece of tissue only is available, choice of preservation lies between fixation and snap freezing (Dawson, 1972a). In Crohn's disease, where the histochemistry of dehydrogenase enzymes is not likely to be important, fixation is preferable (Dawson, 1972b). The biopsy should be placed, mucosal surface upwards, on a glass cover-slip and fixed in 10 per cent neutral or buffered formol–calcium at 4° C. Supplies of the fixative should always be stored, ready prepared, in the correct-sized bottles in a refrigerator near the theatre in preparation for use; it is advantageous to include two or three cover-slips in each bottle. After taking the biopsy the fixed specimen should either be sent at once to the laboratory or be replaced in the refrigerator—but *not* in the ice compartment—and the laboratory notified. The latter technique is particularly applicable to specimens taken out of normal laboratory hours.

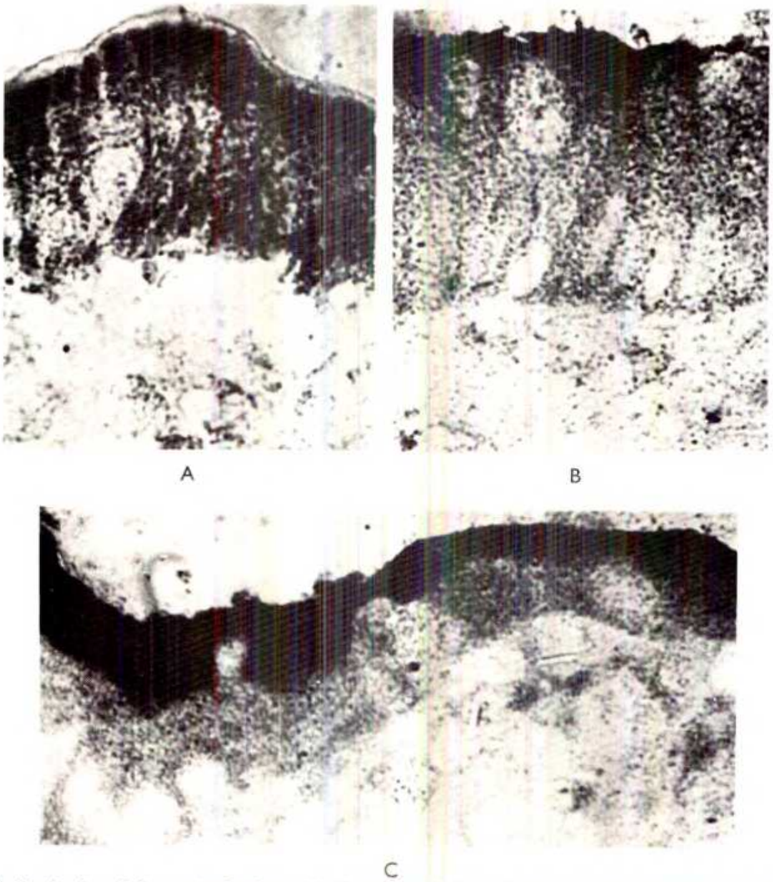

FIG. 1.—A, Normal distribution of glucose-6-phosphate dehydrogenase (G6PD). The finely granular formazan is distributed throughout the cytoplasm of the surface epithelium of rectal mucosa. B, Distribution of G6PD in Crohn's disease. There is a formazan deposit in the upper part of the rectal epithelial cell. C, Distribution of G6PD in ulcerative colitis. The formazan shows as a heavy deposit in the superficial cytoplasm of rectal epithelial cells and there is relatively little in the deeper part. However, the differences between B and C are not great enough to be diagnostic. NADP–tetrazolium technique. (× 200.)

DIAGNOSIS OF CROHN'S DISEASE OF THE LARGE INTESTINE USING RECTAL BIOPSY

Most resected specimens from patients with Crohn's disease have easily recognizable macroscopic and microscopic features and can be diagnosed without difficulty, but problems may arise in rectal biopsies from suspected cases with or without obvious rectal involvement clinically; these fall into four main histological categories:—

1. Biopsies in which the mucosa appears histologically normal. In these one must serially section or step section the block in a search for granulomas; no special investigations are at present of value.

2. An occasional biopsy in which isolated sarcoid-like granulomas are present in an otherwise normal mucosa. Crohn's disease can be strongly suspected but there are no special investigations which will prove it.

3. Biopsies in which sarcoid-like granulomas are present along with mucosal erosion or ulceration, lymphoid aggregates, and other features commonly seen in Crohn's disease. If tuberculosis can be excluded a fairly confident diagnosis can be made.

4. Biopsies in which there is a severe chronic inflammatory reaction in the lamina propria and submucosa, with or without mucosal erosion, ulceration, crypt abscesses, etc., but without a diagnostic sarcoid granulomatous reaction. It is in this group that special investigations can be of diagnostic value; all those which are useful can be undertaken on cold formol–calcium-fixed material.

SPECIAL INVESTIGATIONS FOR DIAGNOSIS

Patients whose biopsies fall into group 4, above, may have Crohn's disease, ulcerative colitis, non-specific proctitis or proctocolitis, or some specific inflammatory disorder. Histochemical techniques for selected enzymes and for mucosubstances have been used in attempts to make a differential diagnosis (Dawson, 1972b).

Enzyme Techniques.—The enzymic pattern in the large intestinal mucosa somewhat resembles that in the basal layer of the small intestine (Dawson and Pryse-Davies, 1963; Melnyk, Braucher, and Kirsner, 1967; Van Noorden, Thayer, Yesner, and Spiro, 1967;

Filipe, 1971). Dehydrogenases and diaphorases with the exception of succinate dehydrogenase are present in a higher concentration in the absorptive cells of the surface epithelium than in the crypts, and the finely granular deposit of formazan which indicates their presence is either diffused throughout the cell or predominantly perinuclear in distribution (*Fig.* 1 A). Various authors, particularly Mendeloff and Monis (1962) and Monis and Mendeloff (1965), described changes in the intracellular distribution of these enzymes in ulcerative colitis, the formazan granules tending to be concentrated immediately beneath the luminal border of each cell (*Fig.* 1 C), and suggested that this could be a useful diagnostic reaction for separating ulcerative colitis from non-specific proctitis and Crohn's disease. Other workers, however, while confirming that such a change in enzyme distribution does take place, believe it to be less specific (Van Noorden and others, 1967). Studies in the present author's laboratory (Filipe, 1971; Dawson, 1972b) show that similar though usually less severe changes can occur in Crohn's disease (*Fig.* 1 B) and in unclassified proctitis and it is believed that they indicate no more than a non-specific reaction in epithelium which is regenerating.

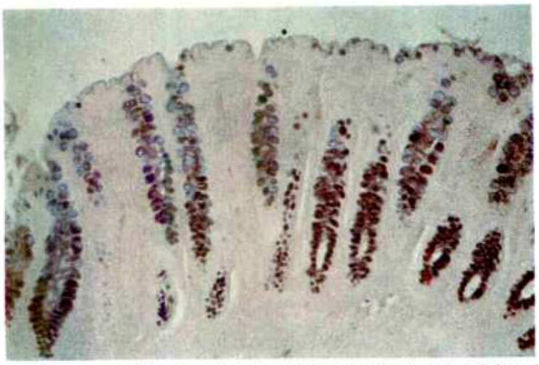

FIG. 2.—Acid non-sulphated (blue staining) and sulphated mucosubstances (brown staining) in normal rectal mucosa. High-iron diamine (HID)–Alcian blue (AB) technique. (× 25.)

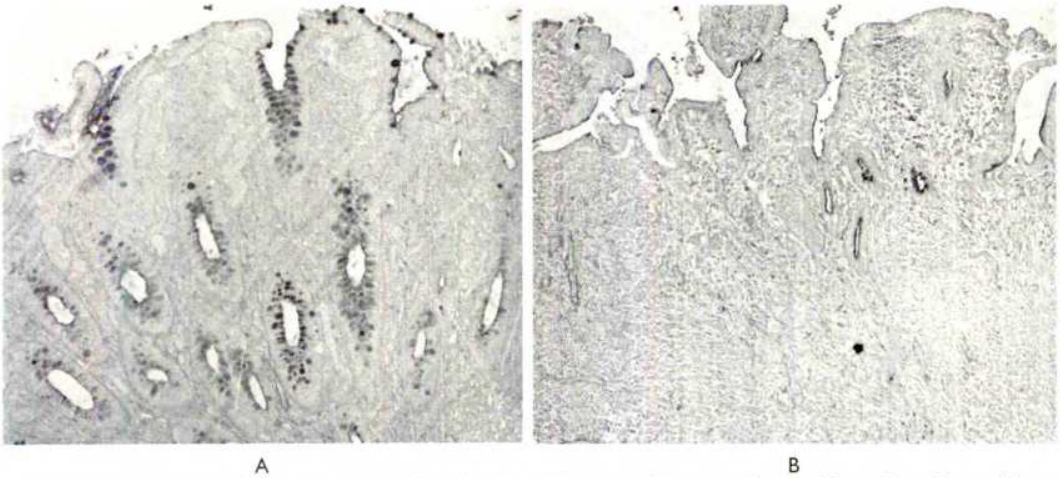

FIG. 3.—A, Rectal mucosa in moderately active ulcerative colitis. There are still some mucin-containing goblet cells remaining. B, Rectal mucosa in severe active ulcerative colitis. Hardly any mucin-containing cells remain. HID–AB. (× 25.)

Techniques for Mucosubstances.—Mucosubstances can be classified histochemically simply, if not entirely accurately, as neutral, acid non-sulphated, and sulphated, using three relatively simple histochemical techniques, namely periodic acid–Schiff (PAS), Alcian blue at pH 2·5, and a high-iron diamine technique, or appropriate combinations. Their normal distribution in the large intestine is well described (Lev and Spicer, 1965; Greco, Lauro, Fabbrini, and Torsoli, 1967; Goldman and Ming, 1968), and most workers, with minor differences, expect to find neutral mucosubstances in the goblet cells of the surface epithelium and the upper one-third of the crypts, acid non-sulphated mucosubstances in the surface epithelium and the upper two-thirds of the crypts, and sulphated mucins in the lower and middle thirds of the crypt rather than on the surface (*Fig.* 2). Studies made on rectal biopsies from patients with ulcerative colitis and Crohn's disease (Greco and others, 1967; Hellstrom and Fischer, 1967; Hradsky, Langr, Nerad, and Skaonic, 1967; Gad, 1969) have shown divergences from the normal pattern in different types of inflammation; in general there is a marked diminution in mucus secretion and goblet-cell

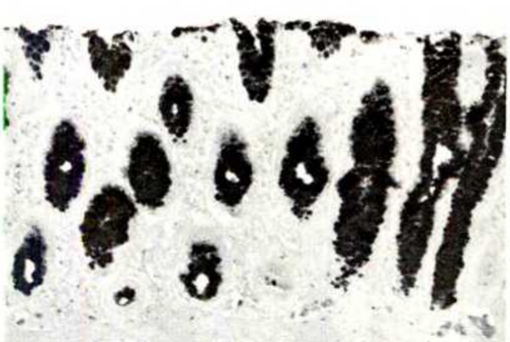

FIG. 4.—Rectal mucosa in Crohn's disease. The mucosubstance pattern is normal. HID–AB. (× 25.)

numbers in ulcerative colitis, a moderate diminution in non-specific proctitis, and little or no diminution in Crohn's disease. Fairly extensive studies by Filipe (1969) and Filipe and Dawson (1970) in general confirm these distributions for rectal mucosa and indicate that the mucosubstances which remain in Crohn's disease are predominantly of the acid non-sulphated type. Far less difference between different inflammatory conditions in colonic mucosa has been found. While I cannot entirely agree with Hellstrom and Fischer (1967) that one can make an accurate differential diagnosis between ulcerative colitis, non-specific proctitis, and Crohn's disease using techniques for mucosubstances, I have found them of definite value in the difficult biopsy.

Electron Microscopy.—The only studies using the electron microscope which I know of in Crohn's disease are those of Aluwihare (1971a, b); these, though of great interest, do not assist in the differentiation of Crohn's disease from ulcerative colitis or proctocolitis. A few incidental unpublished observations made during work done on the value of electron microscopy in detecting precancer in ulcerative colitis (Jenkinson and Dawson, 1971) did not show appreciable differences in individual mucosal cells from different patterns of rectal inflammation.

THE USE OF BIOPSIES AND TISSUES FOR RESEARCH

The aetiology of Crohn's disease remains unknown, but the emphasis in research has shifted towards consideration of it as a manifestation of cell-mediated immunological anergy (Kraft, 1971; Kraft and Kirsner, 1971). Such a suggestion is supported by observations such as those of Mitchell, Cannon, Dyer, Hinson, and Willoughby (1970) that the Kveim test for sarcoidosis, in which disease there is recognized impairment of cell-mediated immunity, is positive or probably positive in 51 per cent of patients with Crohn's disease; that in Crohn's disease there is reduced or absent skin sensitivity to 2-4-dinitrochlorobenzene (Jones, Housley, Ashurst, and Hawkins, 1969); and that lymphocytes from patients with Crohn's disease show a poor *in vitro* transformation response after stimulation with phytohaemagglutinin (Walker and Greaves, 1969; Brown, Taub, Present, and Janowitz, 1970). It is now practicable, using antisera to the human immunoglobulins IgA, IgG, and IgM raised in animals and 'tagged' with either fluorochromes or peroxidase (Petts and Roitt, 1971), to demonstrate in tissue sections of bowel those cells which are synthesizing immunoglobulin, though one cannot reliably distinguish plasma cells which will secrete humoral antibody from lymphocytes which retain cellular antibody in their surface membranes (Pettingale, 1971). Studies have already been made on normal mucosa (Crabbé and Heremans, 1966) and on the mucosa in malabsorption syndromes (Kenrick and Walker-Smith, 1970; Douglas, Crabbé, and Hobbs, 1970) and ulcerative colitis (Hardy Smith and MacPhee, 1971). Similar studies would be practicable on all rectal biopsies which are divisible into two so that fresh-frozen material can be obtained and processed in appropriate ways, and some limited studies might be possible even on formaldehyde-fixed material. These might lead to valuable information, not only as to the aetiology but also in the differential diagnosis of Crohn's disease.

Acknowledgements.—It is a pleasure to thank my colleague, Dr. M. I. Filipe, who did much of the work on mucosubstances; also the technical staff of the Udall Street Laboratories of Westminster Medical School, particularly Mrs. B. Patel and Miss J. Hepple; and Mrs. D. Litinakis for secretarial assistance. Part of the costs of the various investigations were defrayed by the Cancer Research Campaign, the Governors' Discretionary Fund of Westminster Hospital, and a personal research grant from Mr. Maurice Job through the Westminster Hospital Research Trust, all of which I gratefully acknowledge.

SOME ASPECTS OF THE RADIOLOGY OF CROHN'S DISEASE

By K. C. SIMPKINS

DEPARTMENT OF DIAGNOSTIC RADIOLOGY, THE GENERAL INFIRMARY, LEEDS

THE clinical diagnosis of Crohn's disease is often difficult, and many of the lesions are not within reach of inspection. Radiology is, therefore, valuable in establishing the diagnosis and defining the site, severity, and extent of disease. A complete review of the varied techniques of radiological investigation and findings in Crohn's disease is beyond the scope of this paper. Various aspects of the barium examination of the gastro-intestinal tract will be considered, with particular reference to several of the less common small-bowel features and to the differential diagnosis of Crohn's colitis.

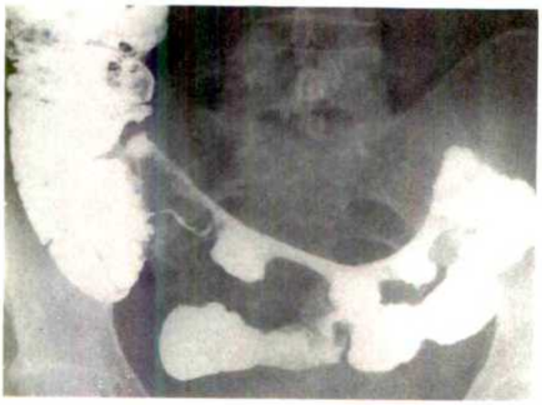

FIG. 1.—Eccentric fibrosis has produced a series of strictures and sacculations resembling a row of hammocks.

SMALL-BOWEL DISEASE

Radiologically, cases may be conveniently divided into either stenotic or non-stenotic types. Strictures which may occur anywhere in the small bowel are often multiple, separated by intervening segments of pre-stenotic dilatation. In the terminal ileum, which is the most frequent site of the disease, narrowing of the lumen by thickening of the wall, or by spasm, produces the classic 'string sign' of Kantor (1934). Occasionally where fibrosis is eccentric and involves a length of one side of the wall a series of 'purse-string' pouches or sacculations is formed along the opposite margin (*Fig.* 1). This feature is not seen in tuberculosis or reticulosis, which in other ways strongly resembles small-bowel Crohn's disease. All these late stenosing lesions are especially liable to be accompanied by fistulae, which occur in about one-third of all the cases of small-bowel disease (Brahme, 1971).

The earliest radiological suspicion of Crohn's disease is irritability of the terminal ileum which is seen on careful screening of the region during the course of a barium-meal examination of the small bowel. Another early sign is a characteristic deformity of the medial wall of the caecum attributable to an oedematous ileocaecal valve, spasm secondary to adjacent ileitis, or extrinsic pressure from enlarged lymph-glands. Although this feature may be the only demonstrable sign of Crohn's disease there are usually associated non-stenotic changes in the terminal ileum consisting of 'cobblestone' mucosa, marginal irregularity, and fissure formation (*Fig.* 2).

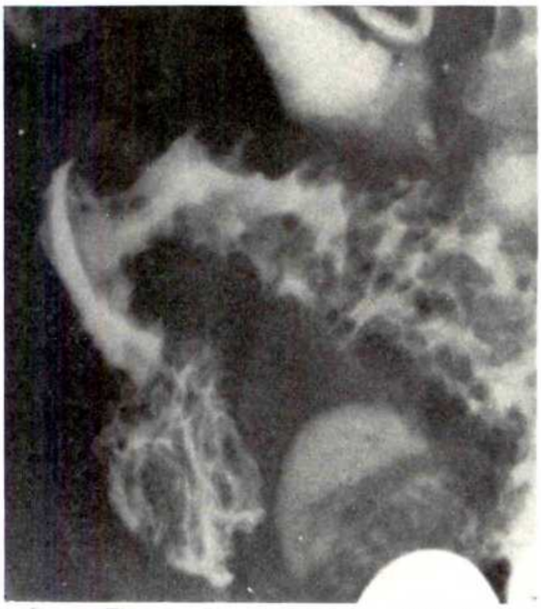

FIG. 2.—There is a curved defect in the medial wall of the caecum at the site of the ileocaecal valve. Non-stenotic changes of Crohn's disease are present in the terminal ileum with 'cobblestone' mucosa and ulceration.

Recurrent disease is a special problem and may occur at an anastomosis following resection of diseased bowel, immediately proximal to an ileostomy, or at a site remote from previous surgery. Radiological investigation is by barium-meal examination of the small bowel, ileal enema through the ileostomy stoma, or barium enema. The features of recurrence are the same as those of the original disease (*Fig.* 3). The radiologist's main problem is becoming familiar with the normal appearances following surgery and there is a strong case for performing base-line barium-meal examinations a few weeks postoperatively on all patients who have had resections for Crohn's disease. Should the patient experience further trouble there is then a previous normal postoperative examination available for comparison.

LARGE-BOWEL DISEASE

The barium-enema diagnosis of colitis, be it ulcerative, Crohn's, ischaemic, or whatever, is usually not difficult. The problem lies in differentiating one type from another, and particularly Crohn's from ulcerative colitis. General features such as narrowing,

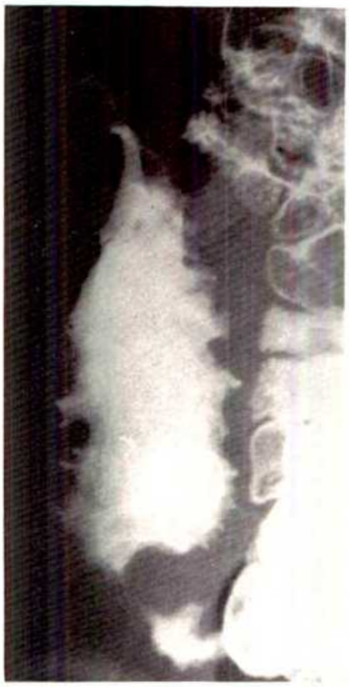

FIG. 3.—A short narrow stricture at the ileostomy stoma (*top left*) and ulceration of the adjacent segment of ileum indicate recurrence of disease.

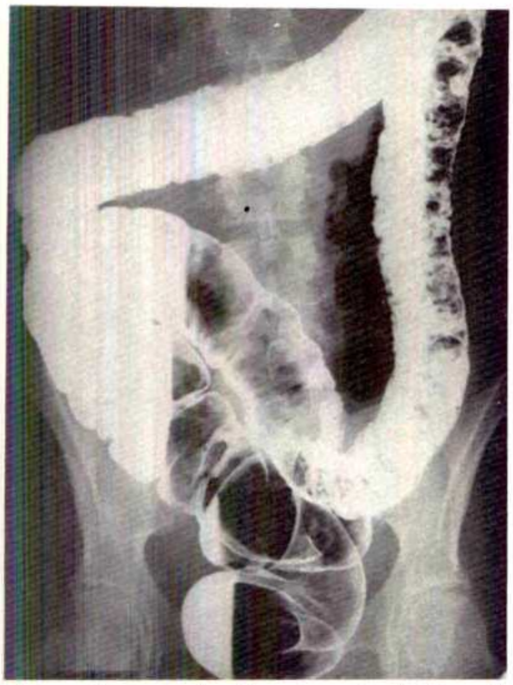

FIG. 4.—Disease involves the colon as far distally as the proximal sigmoid, where there is some eccentric involvement. The rectum and distal sigmoid are normal.

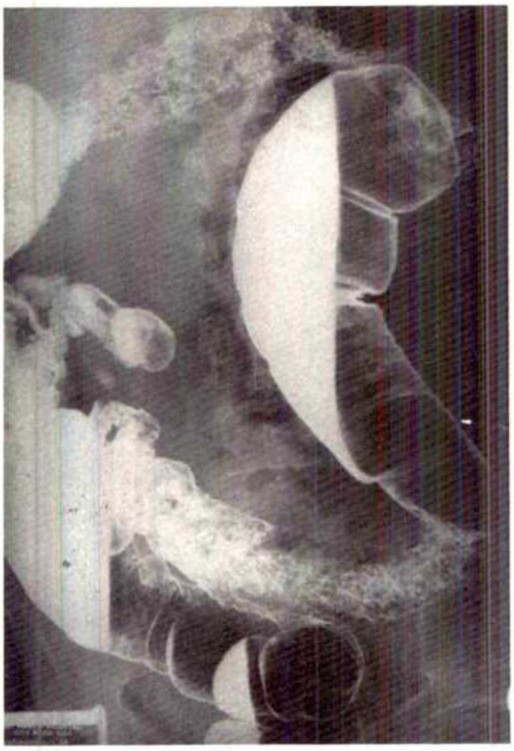

FIG. 5.—Several areas of disease are present, notably in the transverse colon and proximal sigmoid. There is also some eccentric involvement of the distal sigmoid and a patch of ulceration in the mid-descending colon.

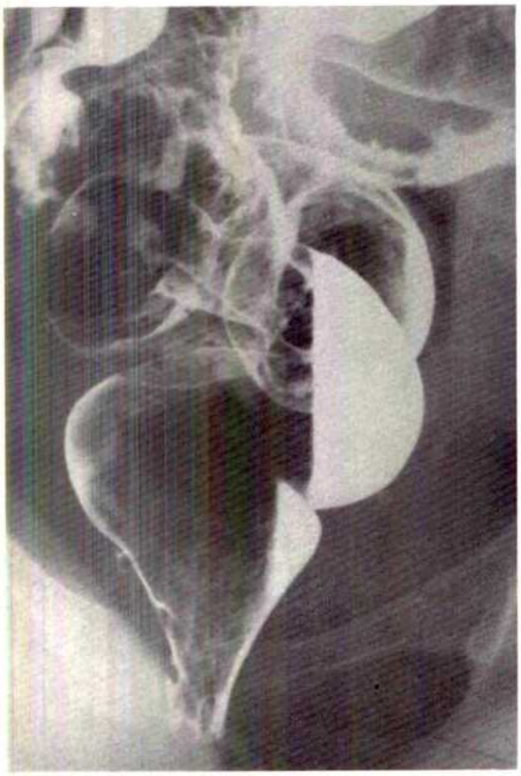

FIG. 6.—A long anorectal ulcer is present and a deep discrete ulcer surrounded by normal mucosa in the right mid-lateral rectal wall. Further disease is seen in the colon.

shortening, and absent or abnormal haustration are sometimes difficult to assess, particularly in borderline cases, and are not helpful in the differential diagnosis. For this purpose the distribution of pathology throughout the colon, rectum, and anus, and the particular features of individual lesions, especially ulcers, are of the greatest assistance in separating Crohn's disease from ulcerative colitis.

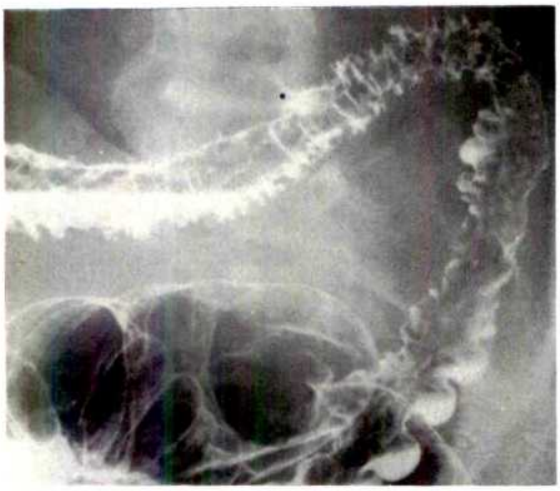

FIG. 7.—There is narrowing of the transverse colon with composite ulcers and fissures. In the proximal descending colon eccentric involvement has produced sacculation of a normal patch of bowel on the medial side. Normal mucosa is seen in the sigmoid.

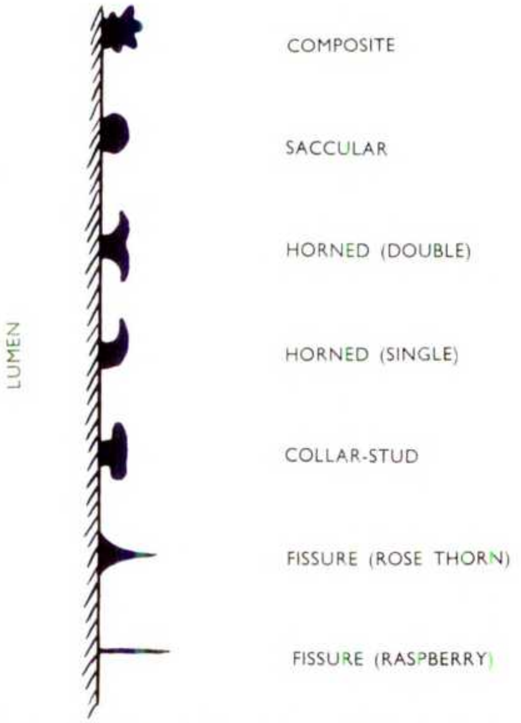

FIG. 9.—Illustrations of the types of ulcer seen in Crohn's colitis.

Distribution of Pathology throughout th Large Bowel.—Crohn's disease involves the rectu in only 50 per cent of cases, has a tendency to b right-sided (*Fig*. 4), and is often discontinuous, wit areas of disease separated by variable lengths of normal bowel ('skip lesions'—*Fig*. 5). In contrast, ulcerative colitis involves the rectum in at least 95 per cent of cases and the disease is in continuity (Lockhart-Mummery and Morson, 1964). In Crohn's disease

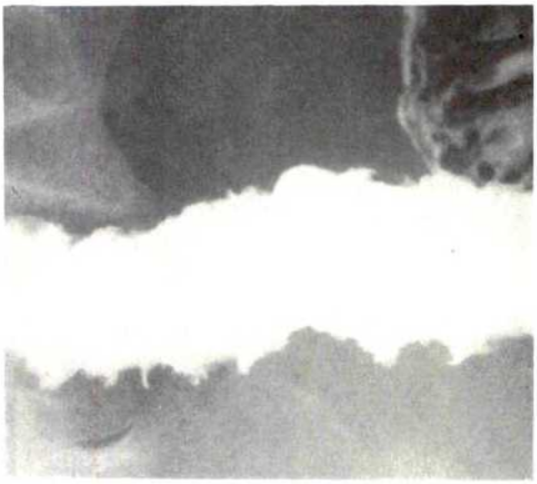

FIG. 8.—A localized view of part of the transverse colon showing several of the characteristic types of Crohn's ulceration, i.e. fissure, horned, and composite.

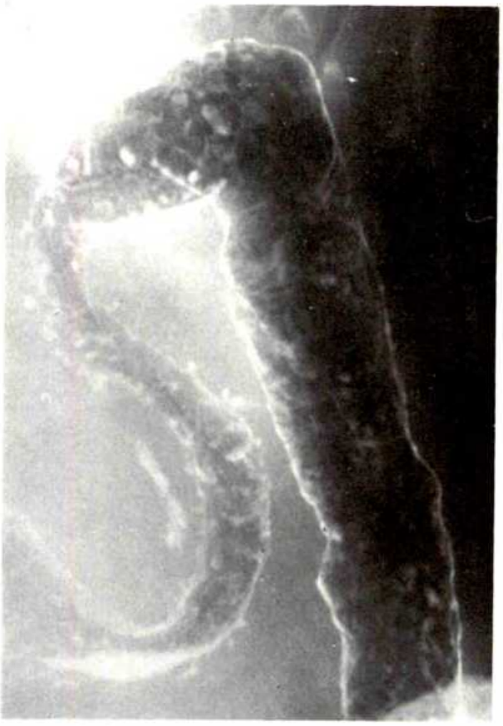

FIG. 10.—Confluent intramural ulceration is present together with narrowing and deep ulceration.

ormal patches of mucosa may be present in the nidst of diseased areas and vice versa, or discrete lcers may be surrounded by an area of normal mucosa (*Fig.* 6). Involvement may be eccentric, sometimes with sacculations of the normal bowel wall produced by contraction of areas of severe disease on the opposite wall (*Fig.* 7). Similar appearances are seen in ischaemic strictures (Marston, Pheils, Lea-Thomas, and Morson, 1966) and scleroderma (Kemp Harper and Jackson, 1965). Rarely, localized scarring

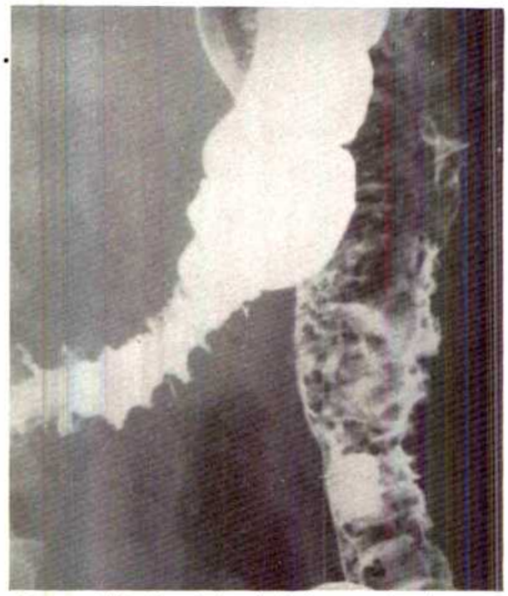

FIG. 11.—This view of the splenic flexure region shows many of the characteristic features of Crohn's colitis. The transverse colon is narrowed with deep fissures and composite and horned ulcers. Similar ulceration is seen in the descending colon together with 'cobblestone' mucosa. The mucosa of the splenic flexure itself looks normal.

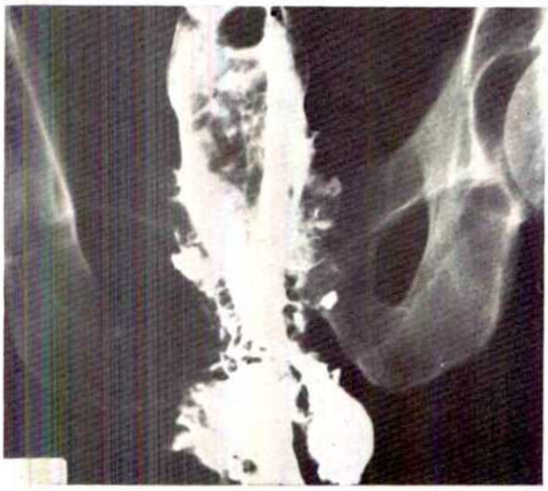

FIG. 12.—Gross anorectal disease is present with fistula and abscess formation. Rectal ulceration is mainly of the fissure variety, both rose-thorn and raspberry-thorn.

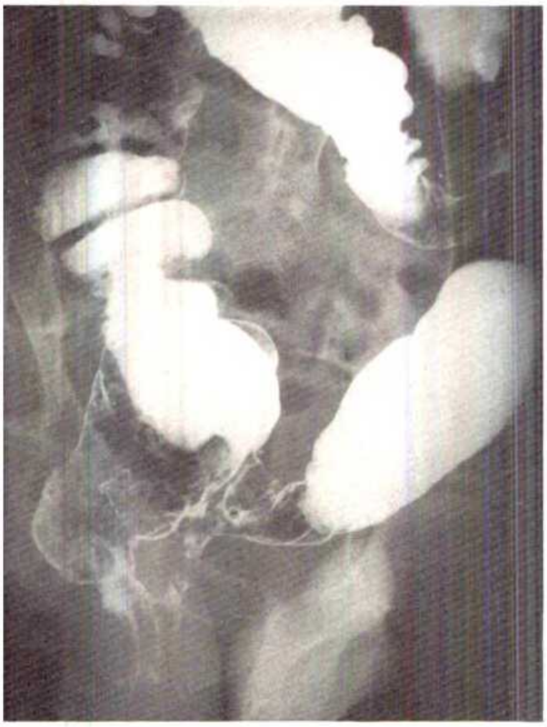

FIG. 13.—There are irregularity and narrowing of the anal canal and lower rectum with a fistula extending from the lower rectum to the sigmoid. A rectocolic fistula is one of the least common varieties in Crohn's disease. A stricture is present at the splenic flexure.

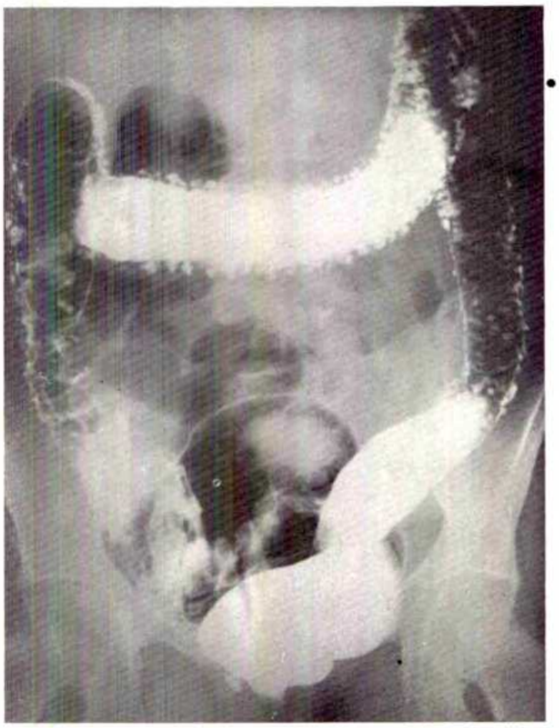

FIG. 14.—Many of the characteristic features of Crohn's colitis are present such as a pararectal abscess, a normal-looking sigmoid with gross changes in the rest of the colon, and deep composite ulceration in the transverse colon. The caecum is contracted and there is probable disease of the terminal ileum.

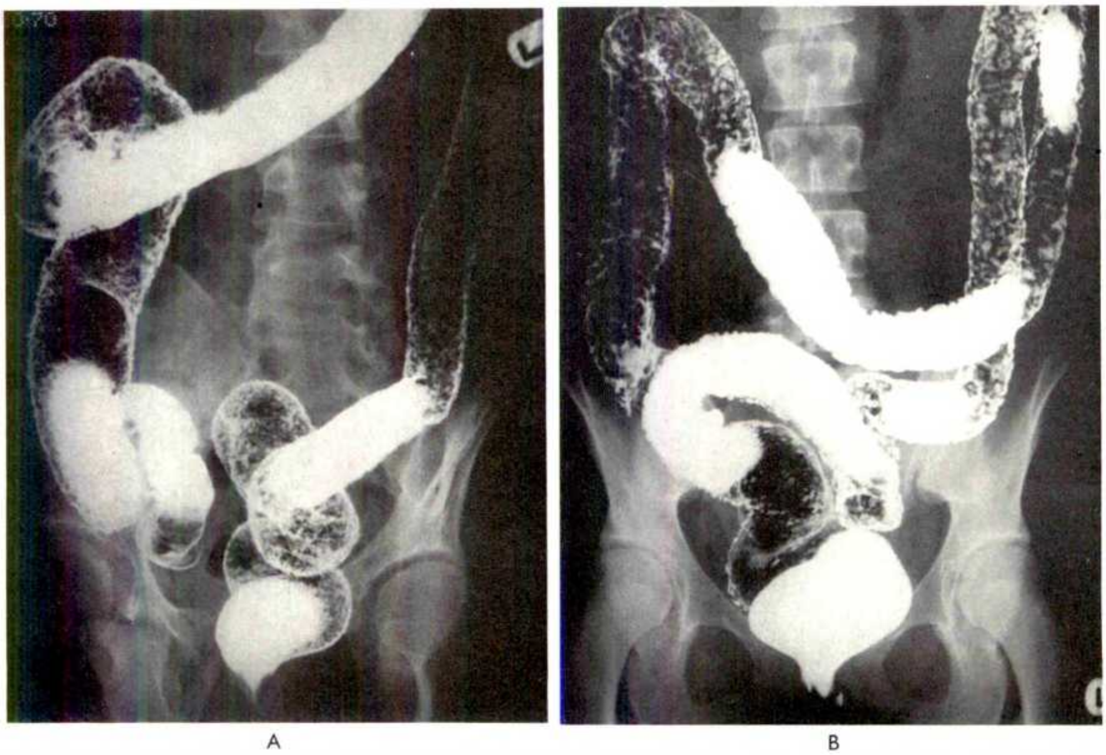

FIG. 15.—A, Shallow ulceration, pseudopolyposis, dilated terminal ileum, and absence of an anal lesion indicate ulcerative colitis. B, Deep pleomorphic ulceration, 'cobblestone' mucosa, and a perianal abscess indicate Crohn's colitis. The ileum was also diseased. There is a strong resemblance between these two examples of total ulcerative colitis and Crohn's disease respectively.

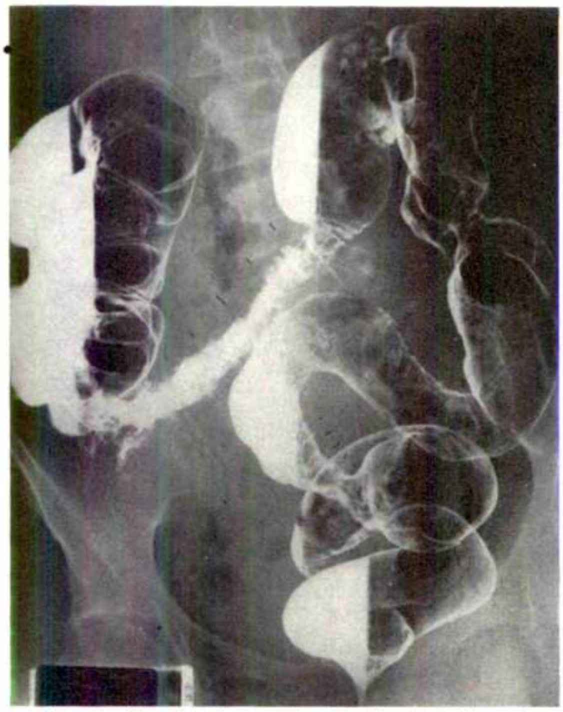

FIG. 16.—Several strictures of various lengths and severity, some with ulceration, are present. An eccentric patch of mucosal disease is seen in the proximal sigmoid and there is a deep discrete ulcer in the right lateral wall of the rectum.

and narrowing of the colon lead to the formation o large false diverticula (Berridge, 1971). Haustratio may be retained in the presence of severe ulceration or eccentric incomplete loss of haustration may occur All these features are at variance with the mor uniform changes of ulcerative colitis.

Features of Individual Lesions.—Of the individual features of Crohn's colitis, the most importan is ulceration because some of the forms that the ulcer may take are characteristic and assist in differentiatio from ulcerative colitis. Occasionally only one type o ulcer is present in an individual case, but usuall ulceration is pleomorphic (*Fig.* 8), unlike ulcerativ colitis where all the ulcers in an individual case ten to be of similar size and shape. Some of the differen types of ulcer are illustrated in *Fig.* 9. Deep ulceratio of more than 3 mm. depth is very strong evidence o Crohn's disease, as are fissures, composite or horne ulcers, and linear intramural confluent ulceratio (*Fig.* 10). A fissure is a deep spicular ulcer, eithe broad-based triangular and rose-thorn, or narro linear and raspberry-thorn in shape, extending int the bowel wall at right-angles to the lumen (Young 1970). A composite ulcer consists of a large saccula ulcer with short finger-like projections resembling sea-mine or cow's udder.

The 'cobblestone' appearance of Crohn's diseas owing to the high-lighting of surviving islands o oedematous mucosa by a network of linear ulceratio and the pseudopolypoid inflammatory changes o ulcerative colitis bear a strong resemblance and ar sometimes indistinguishable (*Fig.* 11).

Anal lesions consisting of anal and perianal swelling, ulceration, abscesses, and fistulae are present at some tage in 75 per cent of the cases of large-bowel Crohn's disease, particularly in those with severe colonic nvolvement and in one-quarter of those cases with mall-gut disease only (Gray, Lockhart-Mummery, nd Morson, 1965). The radiological demonstration of n anal or perianal lesion may be a vital clue to the iagnosis of Crohn's disease as not all of these lesions re previously detected clinically (*Figs.* 6 and 12). imilar changes in ulcerative colitis are considerably ss common and are always accompanied by proctitis. olitis with a normal rectum and an anal lesion is iagnostic of Crohn's disease as the anal pathology an be counted as a skip lesion.

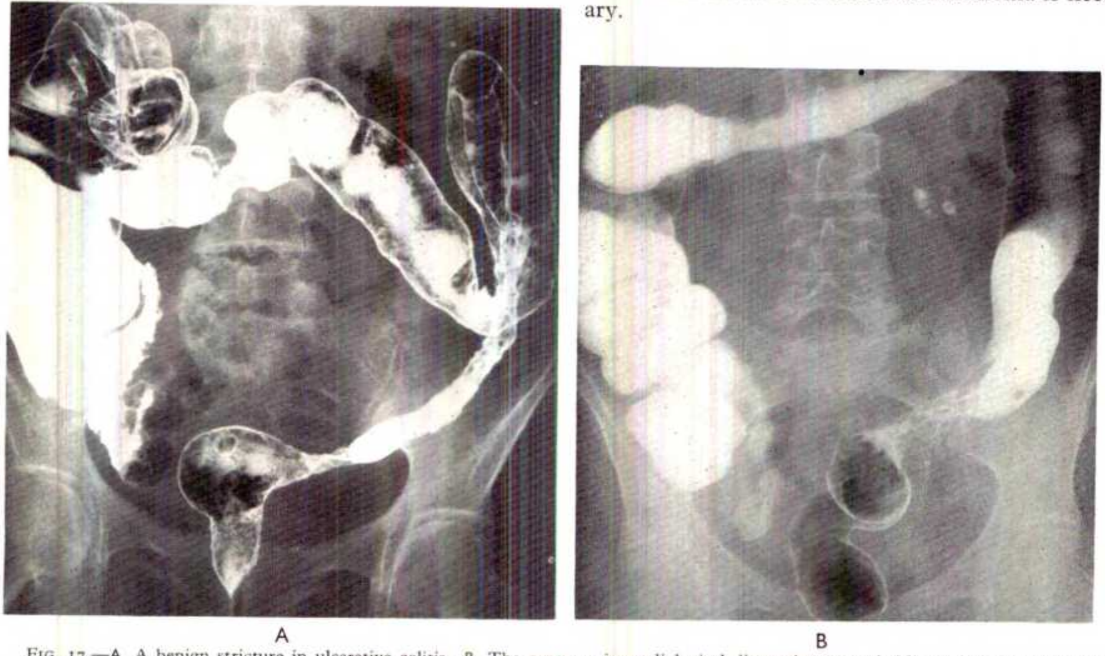

FIG. 17.—A, A benign stricture in ulcerative colitis. B, The preoperative radiological diagnosis was probable carcinoma in ulcerative colitis because irregular intraluminal filling defects are present in the stricture and just proximal to it. However, pathological examination of the colectomy specimen was characteristic of Crohn's disease and there were also some features to suggest additional diverticulitis. There is a strong resemblance between these two examples of extensive long-standing colitis with sigmoid stricture.

able I.—THE LIKELIHOOD OF CROHN'S COLITIS RELATED O ANORECTAL DISEASE AND DISTRIBUTION SEEN ON BARIUM-ENEMA EXAMINATION

DISTRIBUTION			LIKELIHOOD OF CROHN'S COLITIS
Anal Lesion	Proctitis	Colitis	
+	−	+	***
−	−	+	**
+	+	+	*
−	+	+	
−	+	−	
+	+	−	*
iscontinuous disease (skip lesions)			***
ccentric involvement			**
leal lesion			***

* = Possible Crohn's colitis. ** = Likely Crohn's colitis. *** = ery likely Crohn's colitis. The presence of more than one feature om *Tables I* and *II* increases the likelihood of Crohn's disease.

Fistulae are more often a feature of small- than of large-bowel disease. Communication may occur between the gut lumen and the skin or lumen of another viscus (*Fig.* 13). In the pelvis differentiation from diverticulitis and carcinoma is necessary.

Table II.—THE LIKELIHOOD OF CROHN'S COLITIS RELATED TO A VARIETY OF INDIVIDUAL LESIONS SEEN ON BARIUM-ENEMA EXAMINATION

INDIVIDUAL LESIONS	LIKELIHOOD OF CROHN'S COLITIS
Deep ulcers of any form	*
Deep ulcers in the rectum	**
Saccular ulcers	*
Composite or horned ulcers	***
Fissures, either rose-thorn or raspberry-thorn	***
Linear intramural confluent ulceration	***
Discrete ulcers surrounded by an area of normal mucosa	***
Retained haustration in ulcerated bowel	**
'Cobblestone' mucosa	**
Fistula	**

See Table I for key.

SOME DIAGNOSTIC PROBLEMS OF LARGE-BOWEL DISEASE

In the majority of cases assessment of all the available radiological signs allows a confident diagnosis to be made (*Fig.* 14). There are, however, a minority of cases, perhaps of the order of about 5 per cent, where the diagnostic features are uncertain and occasionally frankly misleading. This situation arises if insufficient diagnostic signs are demonstrated, either because they are not present or because radiological examination is not of the necessary quality. Alternatively, clear diagnostic signs may be demonstrated, but are conflicting, favouring different diagnoses. Under these circumstances the problem is knowing to which signs to afford the greatest weighting. An attempt at this has been made in *Tables I* and *II*.

Total Colitis.—This situation removes several of the most helpful signs of Crohn's disease, such as a right-sided distribution with sparing of the rectum and discontinuous, eccentric, or patchy disease. Clues to diagnosis may be found at the two ends of the large bowel, i.e., the ileum and the anus. Involvement of the terminal ileum occurs in about half the cases of Crohn's colitis (Morson, 1971) and is seen as narrowing, often with strictures elsewhere in the small bowel. In ulcerative colitis if the ileum is involved it is dilated ('backwash' ileitis). In the presence of total Crohn's colitis an anal lesion is to be expected and most of them will be seen on barium-enema examination. Study of individual colonic lesions, especially ulcers, and the recognition of other features such as 'cobblestoning' and fistula formation enable the correct diagnosis to be reached in the majority of cases, but there is a small residuum in which differentiation is not possible (*Fig.* 15).

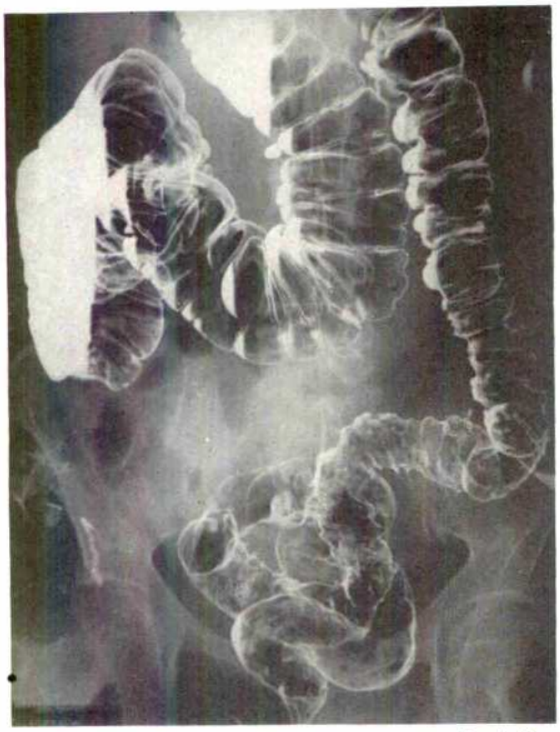

FIG. 18.—At first glance the appearances suggest diverticular disease, but on closer observation not all the barium-filled projections are diverticula. Some of them are deep and spicular, and along the medial wall of the distal descending colon ulceration is of the 'collar-stud' variety. There is therefore coexistent diverticular and Crohn's disease.

Strictures.—These are seen in about one-quarter of cases of Crohn's colitis, being multiple in half of them (Lockhart-Mummery and Morson, 1964). The length, site, and degree of narrowing are variable (*Fig.* 16) (Young, 1970). In most cases the ends are tapered or funnelled. The walls of the stricture may be studded with ulcers, but these are usually absent from long-standing narrow strictures. Many of the strictures of Crohn's disease and ulcerative colitis are indistinguishable so that differentiation is made by assessment of the changes in the remainder of the bowel. Of particular difficulty is the stricture occurring in quiescent or 'burnt-out' colitis (*Fig.* 17). Shouldered ends, ragged channels, and irregular intraluminal filling defects indicate carcinoma and a likely diagnosis of ulcerative colitis. Other conditions which must be included in the differential diagnosis are diverticulitis, ischaemia, irradiation, various extrinsic lesions such as metastasis and abscess tuberculosis, and a variety of tropical diseases (Simpkins and Young, 1971).

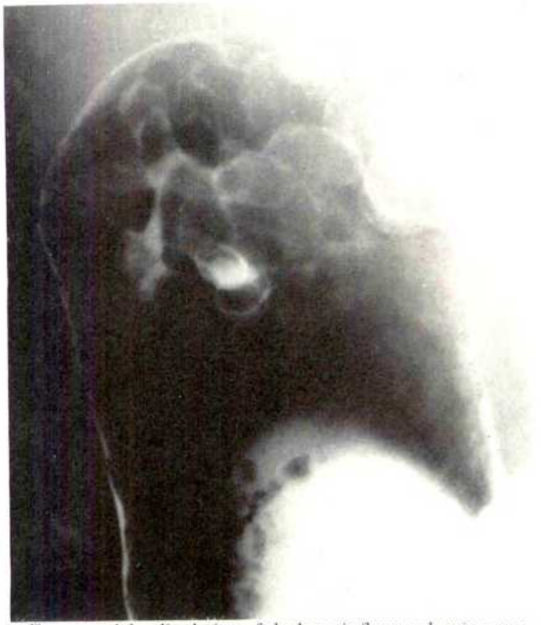

FIG. 19.—A localized view of the hepatic flexure showing complete obstruction by a polypoidal mass of Crohn's granuloma simulating carcinoma.

Coexistent Diverticular Disease.—Schmidt Lennard-Jones, Morson, and Young (1968) have drawn attention to the difficulty in diagnosing Crohn' disease in the presence of diverticular disease and th importance of detecting this combination because o the high incidence of postoperative complications Radiologically, Crohn's disease in the presence o diverticula is suggested by deep narrow fissuring ulceration involving the rectum or colon away fron the area of diverticular disease, linear confluen intramural ulceration, or fistula (*Fig.* 18).

Complete Obstruction.—The granulomatou changes of Crohn's disease may be so prominent tha they produce complete obstruction to the flow o barium on enema examination and simulate th presence of a polypoidal carcinoma (*Fig.* 19). Th demonstration of other changes of Crohn's disease i the colon or small intestine will assist diagnosis, but i their absence differentiation from carcinoma may nc be possible. Similar filling defects in the medial wa of the caecum resembling carcinoma have bee described by Berridge (1971).

Acknowledgements.—I am grateful to the surgeons under whose care the patients were examined. I also wish to thank the Department of Medical Photography of Leeds General Infirmary for preparing the illustrations.

NUTRITIONAL DISTURBANCES IN CROHN'S DISEASE

By A. M. DAWSON

ST. BARTHOLOMEW'S HOSPITAL, LONDON

NUTRITIONAL disturbances are common in Crohn's disease (Cooke, 1955; Pimparker, Mourhan, and Bockus, 1960; Krause, Bergman, and Norlen, 1971). The main manifestations of malnutrition in such patients are weight-loss, anaemia, hypoproteinaemia, electrolyte depletion, and vitamin deficiencies. Furthermore, there are a variety of mechanisms whereby such malnutrition may take place. Thus, there may be a low intake of food because of simple anorexia or fear of aggravating abdominal pain by eating; malabsorption due to either loss of gut surface from inflammation, resection, or surgical by-pass, or the presence of a stagnant loop syndrome caused by strictures, fistulas, or a surgical side-to-side anastomosis. The situation may also be aggravated by excessive loss of protein, blood, electrolytes, and bile-salts from the bowel lumen and also the toxic effect of the inflamed bowel. An analysis of the relative importance of these various factors in 63 patients with Crohn's disease has been published fully elsewhere. There it was concluded that the importance of malabsorption had been overstressed in the past (Dyer and Dawson, 1972a).

WEIGHT-LOSS

Weight-loss is frequent and in childhood may be the cause of a perplexing diagnostic problem, for occasionally adolescent girls may present with weight-loss while the gastro-intestinal symptoms are minimal. On occasion it is difficult to determine whether the weight-loss is in fact due to anorexia nervosa or to an occult intestinal disease (Silverman, 1966). *Fig.* 1 shows the weight chart of such a patient with known Crohn's disease who had minimal symptoms of her disorder and loss of weight. This responded to anti-inflammatory drugs which, of course, would not occur in true anorexia nervosa.

ANAEMIA

The anaemia may theoretically be due to (1) a lack of iron resulting from either impaired intake or excessive loss from the bowel, (2) a lack of vitamin B_{12} caused by resection of inflammation of the ileum or the presence of a stagnant-loop syndrome, and (3) the presence of folate deficiency due to an inadequate intake or increased requirements. In a recent survey (Dyer, Child, Mollin, and Dawson, 1971) of 63 hospitalized patients four-fifths of the men and half of the women were found to be anaemic. Iron deficiency, as determined by bone-marrow examination, was found in 40 per cent of the patients but would have been spuriously diagnosed more frequently if the serum iron and presence of hypochromic cells in the blood-film had been relied on. Vitamin-B_{12} deficiency occurred in 16 per cent of the patients, usually in those who had undergone ileal resection or had extensive ileal disease. Although a stagnant-loop syndrome (Tabaqchali and Booth, 1970) might theoretically be expected to occur frequently, in fact this is a rare mechanism for the genesis of vitamin-B_{12} deficiency (Vince, Dyer, O'Grady, and Dawson, 1972). Folate deficiency is extremely common (Hoffbrand, Stewart, Booth, and Mollin, 1968), as reflected by both a low red-cell count and serum

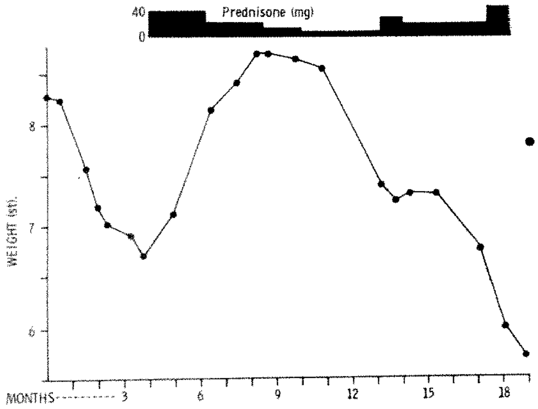

FIG. 1.—Weight-chart of a patient with Crohn's disease who presented initially with weight-loss. The initial response to steroids with subsequent relapse is shown.

folate. It occurs equally in patients who have colonic or small-bowel disease and is far more likely to be due to an impaired intake combined with an increased requirement than to actual malabsorption (Dyer and others, 1972). Occasionally patients have been described whose anaemia responds to oral folate but this has been a rarity.

It would seem that by far the commonest cause of anaemia in patients with Crohn's disease is toxic depression of the marrow.

HYPOPROTEINAEMIA

Fig. 2 shows that patients with Crohn's disease have a far greater depression of the serum albumin than patients with coeliac disease who have an abnormal jejunal mucosa and frequent malabsorption. These results are similar to those reported by Cooke in 1955. If one considers that approximately only 35 g. of protein are needed each day and that most patients are eating much more than this amount, then another mechanism must be invoked to explain the hypoproteinaemia. Furthermore, the serum albumin is reduced whether the patients have ileocolic or diffuse small intestinal disease (*Fig.* 3). These two facts strengthen the view that the commonest cause of hypoproteinaemia is loss of protein from the inflamed bowel into the lumen. This may be digested and reabsorbed but the liver has only a limited capacity to synthesize albumin so that hypoproteinaemia ensues—protein-losing enteropathy (Steinfeld, Davidson, and Gordon, 1960; Waldman, 1970). However, in some patients with profound anorexia true protein deficiency with depletion of all the body stores may be present.

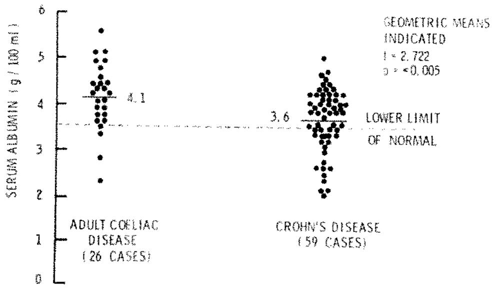

FIG. 2.—Serum albumin in patients with coeliac disease and in those with Crohn's disease (Dyer, 1971).

ELECTROLYTE DEPLETION

Electrolyte depletion occurs as a result of diarrhoea and sometimes steatorrhoea, for the faecal fat is frequently raised in small-bowel Crohn's disease. Its occurrence is most likely due to a disturbance of the bile-salt metabolism. Normally the conjugated bile-salts are not absorbed in the jejunum, in this way maintaining a high concentration of these detergent substances in the lumen of the jejunum from where fat and other lipids are usually absorbed, but these bile-salts are actively absorbed by the ileum, thus preserving the bile-salt pool. This recirculates many times a day and usually only a small amount escapes into the faeces. When the ileum is resected bile-salts are inadequately preserved and an excess escapes into the large bowel where it is degraded into the unconjugated bile-salts and various metabolites (Heaton 1969). These have a cathartic action (Mekhjian Phillips, and Hofmann, 1971). If the resection is large enough and the loss of bile-salts great enough there is an inability of the liver to synthesize adequate replacement and therefore there is a fall in the bile-salt pool with a subsequent decrease in the bile-salt concentration in the lumen of the bowel; steatorrhoea subsequently ensues (Dawson, 1971).

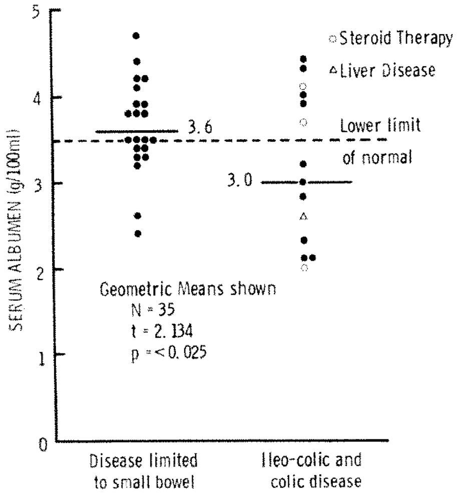

FIG. 3.—Serum albumin in patients with small-bowel disease and in those with ileocolic disease (Dyer, 1971).

The stagnant-loop syndrome occasionally occurs in Crohn's disease but only rarely accounts for the steatorrhoea (Vince and others, 1972). It is of some interest that the steatorrhoea, in spite of being due to bile-salt deficiency, is rarely accompanied by osteomalacia (vitamin-D deficiency) or a prolonged prothrombin time. In fact, when a high alkaline phosphatase is found in patients with Crohn's disease it usually represents impaired liver function (Dyer and Dawson, 1972b) rather than bone disease.

THE MANAGEMENT OF NUTRITIONAL DISTURBANCES

The most important factor is to control the degree of inflammation present either by resection or by suppression of the inflammatory reaction with steroids or possibly azathioprine (*see* article by Rhodes, p. 819). This leads to an improved appetite and a decrease in the nutritional requirement.

Anaemia.—If vitamin-B_{12} deficiency has been demonstrated and malabsorption confirmed by, for example, the Schilling test, monthly injections of vitamin B_{12} will be needed. It is rare that folate supplements will be indicated, for once the appetite returns and the inflammation is removed the serum folate returns to normal. Occasionally iron supplements are of importance, but the presence of a slightly hypochromic film and a low-iron-binding capacity may give a misleading impression that the patient is suffering from iron deficiency when, in fact, he is suffering from a depressed iron uptake by cells in the marrow.

Hypoproteinaemia.—The very nature of the hypoproteinaemia means that a high-protein diet will usually be of little help in such patients if the dominant cause of the hypoproteinaemia is loss of protein into the bowel with inability of the liver to resynthesize. However, in the few patients who are truly protein-depleted an adequate protein intake is important. Furthermore, protein malabsorption may be aggravated by gross steatorrhoea (Pinter, McClaken, Lamar, and Goldsmith, 1964), and control of the steatorrhoea often helps the protein status of the patient.

Very occasionally intravenous salt-poor albumin or amino-acid mixtures and calories may be needed to improve the nutritional status of the patient, but this type of régime is probably being used excessively at the moment.

Steatorrhoea and Diarrhoea.—These are best controlled by a low-fat diet (less than 40 g.), and only rarely are antibiotics of help if a stagnant-loop syndrome should have been demonstrated. Diarrhoea may be helped by the control of steatorrhoea, the use of simple anti-diarrhoeal agents, such as codeine phosphate, or the administration of Lomotil. If the diarrhoea is due to irritation of the colon from unabsorbed bile-salts then cholestyramine (Questran), up to 4 g. q.i.d., can occasionally give impressively helpful results. Unabsorbed bile-salts are less likely to be present if gross steatorrhoea is also a factor (Hofmann and Poley, 1969). If the diarrhoea is severe potassium supplements may be needed.

AZATHIOPRINE IN THE TREATMENT OF CROHN'S DISEASE

BY J. RHODES

DEPARTMENT OF GASTROENTEROLOGY, UNIVERSITY HOSPITAL OF WALES, CARDIFF

As long as the cause of Crohn's disease remains obscure, treatment must be given on an empirical basis. Recently, attempts have been made to explain the disease in immunological terms, and there have been reports of abnormalities in both cellular and humoral immunity (Kraft, 1971; Kraft and Kirsner, 1971). Because of these findings, together with the all too frequent failure of current therapy to control the disease, immunosuppressive drugs, usually azathioprine, have been tried. There have been 14 published studies, which include about 160 patients, in the past 3 years (Avery Jones, Brown, Lennard-Jones, Hywel Jones, and Milton-Thompson, 1969; Brooke, Hoffmann, and Swarbrick, 1969; Brooke, Javett, and Davison, 1970; Brown and Achkar, 1970; Drucker and Jeejeebhoy, 1970; Arden Jones, 1971; Fausa and Gjone, 1971; Rhodes, Bainton, Beck, and Campbell, 1971; Willoughby, Kumar, Beckett, and Dawson, 1971). The possible clinical indications for treatment with azathioprine have included ill patients (some severely ill and others with abdominal fistulae), patients receiving prednisone where an attempt has been made either to reduce or to withdraw the steroid and patients before and after surgery, in the hope of reducing operative complications and recurrence of the disease. Most of these studies have been uncontrolled and for this reason may give a biased account in favour of the treatment.

There are only two controlled trials of therapy in Crohn's disease, both of them with azathioprine. The lack of previous trials in this condition is perhaps a reflection of the difficulties inherent in such a study.

AZATHIOPRINE IN PATIENTS WITH ACTIVE DISEASE

In a double-blind cross-over trial patients were given azathioprine (4 mg. per kg. for 10 days and 2 mg. per kg. thereafter) for 2 months and a placebo for 2 months, the sequence of the treatment periods being made on a random basis (Rhodes and others, 1971). Activity was based on clinical and biochemical features, while progress during the trial was based on the patient's assessment of symptoms together with several laboratory measurements. Changes in the body-weight were noted and patients recorded on a diary card the frequency of stools and colic.

Sixteen patients were admitted to the trial. Six had fistulae (4 on to the abdominal wall, 1 vesicocolic, and 1 perianal). Two patients were dwarfs with recurrent colic. One patient had severe rectal disease with a stricture, and the remaining 7 patients had weight-loss with diarrhoea as a prominent feature. Eight of the patients could be described as 'quite unwell' during the trial.

Fourteen patients completed the trial and a further patient had treatment in both periods. If the progress during the period of azathioprine is compared with that during the placebo period, in 6 patients there was no difference between the periods, 7 patients were better with the placebo, while 2 were better with azathioprine. If the periods are considered separately, with azathioprine 7 patients showed no change in symptoms, 6 deteriorated, and 2 improved. The corresponding figures for the placebo period were 11, 1, and 2 (possibly 3) respectively. In no patient did azathioprine cause a striking improvement, but 2 patients showed a marked deterioration (1 was the result of an allergic arthritis and the other was caused by severe colic which resolved when the drug was withdrawn).

AZATHIOPRINE FOR PATIENTS DURING A STEROID-INDUCED REMISSION

In another double-blind controlled trial patients were treated on a random basis with either azathioprine or placebo for up to 24 weeks (Willoughby and others, 1971). All the patients were in remission and receiving prednisone. One group of 12 patients had recently had an acute illness which had responded to prednisone; the second group of 10 out-patients were on maintenance therapy with up to 15 mg. of prednisone daily. Progress of the patients was assessed clinically and confirmed by a 'disease-activity score' based on the clinical and laboratory data.

Azathioprine in a daily dose of 4 mg. per kg. was given for 10 days and 2 mg. per kg. thereafter. In the first group of patients who were recovering from an acute illness the dose of prednisone was reduced when a remission had been obtained. Azathioprine was started and an attempt was made to discontinue the steroids about 4 weeks later. The second group of patients who appeared to require maintenance treatment with prednisone had this drug discontinued after 4 weeks of azathioprine. If deterioration in the symptoms occured and it was considered necessary to change the treatment the patient was withdrawn from the trial. Ten out of the 11 patients receiving azathioprine completed the 24-week period of the trial compared with only 3 out of the 11 on a placebo, a highly significant advantage in favour of azathioprine. This difference applied to both groups, for the improvement brought about by steroids in those who had recently had an acute illness was maintained by azathioprine.

EARLY AND POSSIBLE LATE COMPLICATIONS OF AZATHIOPRINE THERAPY

The incidence of the short-term complications of leucopenia and thrombocytopenia is probably related to the dosage and seems to occur more commonly with 4 mg. per kg. per day than with 2 mg. Leucopenia is seldom a problem in clinical management when blood-counts are made regularly. However, septicaemia and intra-abdominal abscesses have been reported for treatment with azathioprine (Brooke and others, 1970; Northfield and Roberts, 1972). Although these complications may have occurred without azathioprine therapy, it is difficult to exonerate azathioprine and the associated leucopenia from having played a contributory role.

A severe polyarthralgia and fever have been reported in several patients after about 10 days of therapy We encountered this complication in 2 out of 2 patients while others have not recorded the problem with larger series. The complication appears to be due to a sensitivity reaction and we were unable to resume the drug.

Azathioprine may cause a deterioration in some patients. One of our patients had to discontinue treatment because of very severe small intestinal colic while a second patient complained that the fistulous discharge from his abdominal wall was worse than i had ever been previously.

The long-term consequences of immunosuppression in Crohn's disease are unknown. Even without azathioprine therapy, malignancy has been reported as a complication in both small and large intestinal disease. One must ask whether the risk o malignancy is increased by long-term azathioprine and if so whether the risk is justifiable in view of the possible benefit from the drug. Malignancies, particularly lymphoma, have been reported in recipients of renal transplants on immunosuppressive régimes (Penn and Starzl, 1970). There are only 4 reports o malignancy associated with azathioprine therapy in clinical situations other than in patients who have had transplantations. Experimental work on New Zealand black mice has shown that the incidence of lymphoma in these lymphoma-prone mice is significantly increased by azathioprine, possibly due to depression of the cellular reactivity (Krueger, Malmgren, and Berard, 1971). The *in vivo* cell reactivity, particularly of 'T' lymphocytes, is thought to be of importance in immunological surveillance and control of potentially malignant-cell lines; azathioprine probably depresses these 'T' cells and steroids have a similar effect Patients with Crohn's disease already have impaired *in vitro* 'T'-cell reactivity and *in vivo* depressed delayed hypersensitivity reactions. In Crohn's disease therefore, there is an increased risk of malignancy associated with impaired cellular immunity; both azathioprine and steroids may further depress the cellular response. We have no measure of this cumulative effect but should be aware of its existence

THE POSSIBLE PLACE OF AZATHIOPRINE

In view of the complications which have been associated with azathioprine it is perhaps better reserved for patients who are resistant to other therapy. It may be safer to use only 2 mg. per kg. per day and in combination with a small dose of steroids. I am reluctant to use the compound as the first drug of choice in ill patients. There is no way of predicting those patients (a minority) who may show a favourable response. Steroids appear to help most of the patients in this clinical situation without carrying the special hazards associated with azathioprine.

However, once a clinical remission has been obtained with steroids a special group of patients appears to be delineated who may benefit from the drug. In this situation azathioprine appears to be effective and may be used either to reduce or to discontinue the steroid therapy. At present I should not readily recommend its use as the sole drug in other clinical situations However, there are reports of a favourable response in many other groups of patients: those with extensive inoperable disease, those with fistulae (both abdominal and perianal), those with recurrent disease after previous surgery, and those with systemic manifestations such as pyoderma gangraenosum.

The use of immunosuppressive therapy in Crohn's disease is a situation which is not unique in clinical medicine, although one must feel a little uncomfortable about it. The cause of the disease and the action of the agents that are used in its treatment are both unknown. The response of patients is unpredictable and the long-term hazards are, as yet, undefined. In spite of these obstacles there may well be a place for immunosuppressive therapy in the treatment of Crohn's disease—a place which must be further defined by careful, long-term clinical trials.

SURGICAL TREATMENT OF CROHN'S DISEASE OF THE SMALL INTESTINE

By JAMES KYLE

DEPARTMENT OF SURGERY, UNIVERSITY OF ABERDEEN

The most common site for Crohn's disease is in the distal part of the small intestine. In a typical case the ileal wall is thickened over a distance of 10–20 cm. Sometimes there are short skip lesions which are within a few centimetres of the main mass and which, surgically, may be considered as part of it. A remote skip lesion in the proximal ileum or jejunum occurs in 12 per cent of cases. In the majority of patients the transmural inflammation extends distally as far as the ileocaecal valve. Frequently the caecum and the adjacent ascending colon are healthy, but in some patients their walls are also involved by the granulomatous process.

The onset of Crohn's disease is gradual in most cases, with increasing diarrhoea, abdominal colic, and weight-loss. Ten per cent of cases begin acutely and the presentation may closely simulate that of acute appendicitis. Undoubtedly there are other forms of acute ileitis which are distinct from Crohn's disease and which resolve spontaneously.

Modern medical treatment with corticosteroids and azathioprine can often induce a remission in the chronic inflammatory process, but there is no convincing evidence that it ever produces a permanent cure. Drug treatment may well be required for the remainder of the patient's life if he is to be kept free of symptoms. There are dangers inherent in this course and many people will not accept it. Elective surgical resection is safer and more certain but it is not a guarantee of cure in Crohn's disease.

ACUTE ONSET OF CROHN'S DISEASE

When a short history and clear signs of inflammation in the right iliac fossa make a diagnosis of suppurative appendicitis seem probable, laparotomy is essential. An inexperienced operator may have some difficulty in determining the true nature of the ileal lesion. In most cases the inflammatory mass is simply returned to the abdomen. No attempt should be made to take a biopsy specimen from it, and examination of segments from enlarged mesenteric lymph-nodes is not often rewarding. It is advisable to remove the appendix provided that the caecal wall is healthy. During the years that follow the patient will possibly suffer further attacks of abdominal pain; in these circumstances it is reassuring to know that the appendix is no longer present. The risk of a fistula developing after an appendicectomy performed according to the above criterion is virtually nil (Atwell, Duthie, and Goligher, 1965).

A marked degree of intestinal obstruction is rare in a first attack. Short-circuit with exclusion (*see below*) is probably the treatment of choice.

INDICATIONS FOR OPERATION IN CHRONIC CROHN'S DISEASE

The principal indications for elective operation are set out in *Table I*. The ideal lesion for resection is one that is well localized, which has not progressed, and which has remained quiescent for many months. Any previous complication greatly strengthens the argument in favour of operation. When more than 50 per cent of the small intestine is seen to be diseased, the remaining portion must be suspect. This type of case is generally unsuitable for resection and should be treated medically.

In children and young adults retardation of growth and sexual development and inability really to enjoy life are important considerations. Patients who have had Crohn's disease have a right to expect to be able to indulge in (almost) all normal activities. Recurrent bouts of subacute obstruction strongly suggest that operation is necessary. Continuous loss of blood and protein from ulcerated mucosa may only be stopped by resecting the affected segment. A mass may simulate an appendix abscess or a carcinoma and most patients would wish to be rid of it. External fistulae on the abdominal wall are a nuisance, and while some respond to azathioprine many require resection of the underlying diseased bowel. Remote toxic manifestation in skin, eyes, and joints may likewise fail to respond until all the inflamed intestine has been excised.

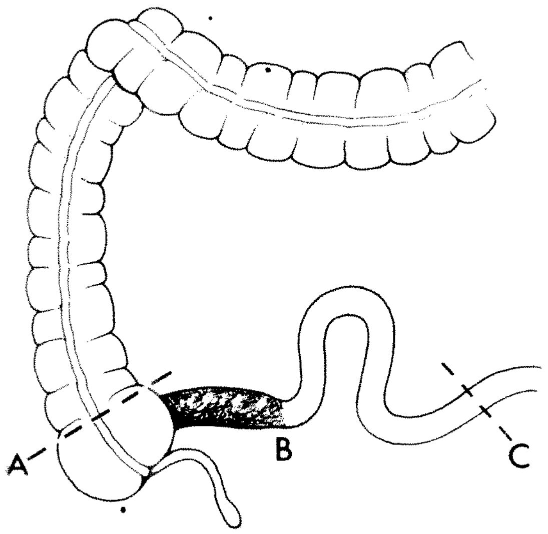

FIG. 1.—Resection of Crohn's disease of the terminal ileum. The colon is transected at A. The upper limit of disease (B) is 20 cm. beyond the point C where healthy ileum is divided obliquely.

Table I.—INDICATIONS FOR ELECTIVE RESECTION IN CHRONIC CROHN'S DISEASE OF THE ILEUM

1. Localized, quiescent disease
2. Failure of adequate medical therapy
3. Inability to enjoy life, retardation of growth
4. Sub-acute intestinal obstruction
5. Persistent anaemia, hypoproteinaemia
6. Abdominal mass
7. External abdominal fistulae
8. Complications in the skin, eyes, and joints

ELECTIVE RESECTION OF ILEUM

The abdomen is opened through a lower right paramedian incision. A careful inspection is made of the entire length of the gastro-intestinal tract and the distribution of any enlarged mesenteric nodes is noted. With disease confined to the lower ileum the aim is to conserve as much of the water-absorbing mucosa of the colon as possible, while removing at least 20 cm. of what looks like healthy ileum proximal to the upper limit of the disease (*Fig.* 1). Leakage may be the immediate result of any attempt to incorporate inflamed intestine in an anastomosis. Even if such an anastomosis remains watertight, reactivation of the disease process soon leads to the reappearance c troublesome symptoms.

A suitable point on the ileum about 20 cm. abov the thickened, red segment (or a closely related ski lesion) is marked with a Babcock's forceps. The ileocaecal part of the intestine is mobilized so that the resection and anastomosis are performed outside the abdominal wall. The line of division of the mesentery is then selected. With a thin mesentery it passes straight from the marked point on the ileum to the start of the ascending colon immediately beyond the ileocaecal valve. If the caecal or adjacent colonic wall is unhealthy a formal right hemicolectomy is necessary With a grossly thickened mesentery and large lymph-nodes it is much safer to keep close to the ileum leaving the nodes behind. When thick, oedematous bites of tissue are held in Mayo's artery forceps it is advisable to transfix them before tying them off.

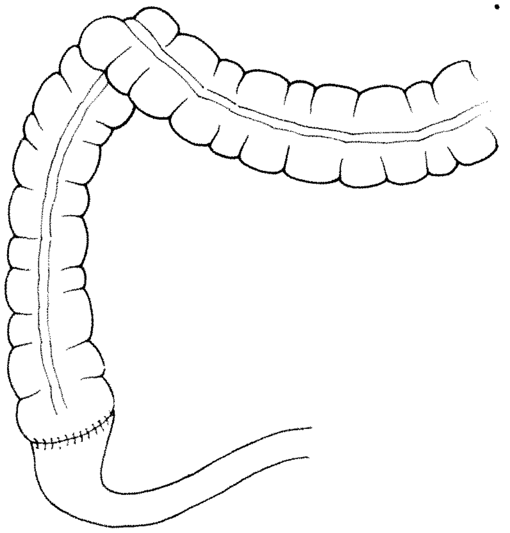

FIG. 2.—The completed anastomosis of healthy ileum to ascending colon.

At least 1 cm. of the circumference of both healthy ileum and ascending colon are cleared of fat mesentery, etc., so that muscle suitable for holding the stitches of the anastomosis is clearly seen. A fine-bladed Schoemaker crushing clamp is placed obliquely across the cleared ileum so that more of the anti-mesenteric wall will be removed; another clamp is applied distally and straight across the ileum. The triangular, uncrushed piece of ileum between the pairs of clamps is sent for histological examination to ascertain if it is free from disease. The commencement of the ascending colon is divided transversely between further pairs of Schoemaker clamps and the specimen is removed.

A few interrupted silk stitches are inserted between the posterior outer surfaces of the obliquely cut ileum and ascending colon. The medial and lateral stitches act as stays and those between help to approximate the somewhat unequal ends of the intestines. Soft occlusion clamps are applied to the two parts of the intestine several centimetres clear of the anastomosis. The Schoemaker clamps are removed and the ends are gently prised open and swabbed clean. A careful search is made for any evidence of aphthoid ulcers on the mucosa surfaces. If any are found an additional 5 cm. of intestine should be removed and the inspection repeated.

A two-layer anastomosis is then made, using outer interrupted silk stitches with an inner continuous locked catgut stitch (*Fig*. 2). It is important to see exactly where every stitch goes and to make sure that the ends of each layer are carefully infolded. The stitches should be 3–4 mm. apart. The silk stay stitches may be used to rotate the anastomosis through 180° to enable the outer posterior layer to be completed before the gap in the mesentery is closed.

SHORT-CIRCUIT WITH EXCLUSION

This operation is performed when resection seems indicated but the findings in the abdominal cavity and pelvis suggest that radical surgery would be unduly hazardous. There may be a large inflammatory mass stuck down in the pelvis against the iliac blood-vessels and ureter, or there may be dense adhesions from a previous operation. Staying well over to the left, out of harm's way, may be a less heroic but is probably a safer course of action in a poor-risk patient. The surgeon who is confronted by acute, complete intestinal obstruction, with inflamed terminal ileum, may also consider it advisable to divide and close the ileum 20 cm. above the diseased segment and then restore intestinal continuity with an ileotransverse anastomosis.

SKIP LESIONS

Skip lesions close to the main mass are resected along with it. One remote skip lesion may be resected or by-passed. There is rarely justification for having more than two anastomoses in series. When several skip lesions are present it is wiser to regard the whole of the small intestine as being diseased and to treat the case medically. A protein-losing or stenotic segment may still merit resection, the other lesions being controlled by drugs.

EXTERNAL FISTULAE

External fistulae nearly always follow a previous abdominal operation or drainage of an abscess. Care is required in opening the peritoneum so as not to damage adherent intestine. Often the inflamed mass can be pinched off the parietes, the track through the abdominal muscles being simply curetted. Sometimes there is a fine fibrous strand running backwards towards the diseased ileum; this is easily divided.

A broken-down anastomosis is a much more serious problem and acts like an uncontrollable ileostomy. It requires, as a matter of urgency, either a re-resection or establishment of a proper, perhaps temporary, ileostomy. Intravenous feeding may be required.

PROGNOSIS

The operative mortality should be less than 2 per cent. On following up those at risk the true recurrence rate at 5 years is 18 per cent following primary resection for ileal disease (Kyle, 1971). At 10 years the rate is 33 per cent. Recurrences may take place 10–20 years after operation. Females under 30 years of age and with short histories tend to fare worse. The erythrocyte sedimentation rate and the presence of lymph-node enlargement, or of a granulomatous reaction in the bowel wall, do not appear to affect the prognosis.

Short-circuit with exclusion produces less satisfactory results. However, an ill patient who had a technically dangerous lesion is still alive. The recurrence rate is more than 50 per cent greater than that with resection, and various types of anaemia may develop. There has been no trouble with 'blown stumps' and resection at a later date is always possible.

CROHN'S DISEASE OF THE LARGE BOWEL

BY H. E. LOCKHART-MUMMERY
ST. MARK'S HOSPITAL AND ST. THOMAS'S HOSPITAL, LONDON

IN trying to discuss some aspects of Crohn's disease as it affects the large bowel I have naturally sought help from the collective experience at St. Mark's Hospital. In the past 20 years 371 new cases of Crohn's disease have been treated at St. Mark's Hospital, but as the cases referred there are predominantly large-bowel problems the distribution of the disease seen is not representative of the pattern of Crohn's disease in the country as a whole. The figures from the Birmingham series compiled by Cooke and quoted by Morson (1971) suggested that about 17 per cent of patients with Crohn's disease had involvement of the large bowel only, and a further 17 per cent had involvement of the small and large bowels, so that in about a third of all cases the large bowel was affected. Classification of the sites of involvement in Crohn's disease is very difficult, but an attempt to do this in 371 new patients seen at St. Mark's Hospital in the past 20 years is shown in *Table I*. The patients were new in the sense that no excisional or by-pass surgery had been undertaken before referral and the sites of involvement were those found at the time of the initial investigation. Fifty-one patients had involvement of the small bowel only, in 86 cases there was disease in the small and large bowels, while in 213 patients the disease was apparently confined to the large bowel, a percentage of 57 per cent compared with Cooke's figure of 17 per cent (Morson, 1971).

Analysis of the age distribution of these cases according to the sites of involvement has produced some rather interesting figures (*Fig.* 1). It will be seen that the patients with small-bowel involvement or with disease involving the small bowel and any part of the large bowel are mainly in the younger age-groups, those with extensive colonic disease but no small-bowel disease show a fairly uniform spread over all the age-groups, whereas those with disease confined to the distal colon and rectum are mainly in the older age-groups, although we have seen some young patients with this rather unusual form of the disease. These figures can perhaps be put more succinctly by saying that in the first group (small intestine ± colon) 85 per cent of the patients were under 45 years of age, whereas in the third group (rectum ± sigmoid and localized colon) more than 70 per cent were over 45 years of age.

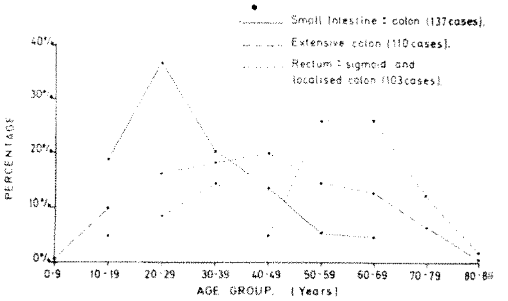

FIG. 1.—Age distribution and sites of involvement in 350 cases of Crohn's disease.

Table I.—SITES OF INVOLVEMENT AT INITIAL PRESENTATION

Site	*No. of Patients*	*Percentage*
Small intestine only	51	13·7
Small intestine and colon	86	23·2
Extensive disease of colon	110	29·7
Localized disease of colon	18	4·8
Rectum ± sigmoid colon	85	22·9
Anus only	21	5·7
Total	371	100·0

To turn now to a few points in the diagnosis of large-bowel Crohn's disease. The many points of difference between large-bowel Crohn's disease and ulcerative colitis have been stated frequently and do not need to be repeated here. In the majority of cases the distinction can be made fairly confidently on clinical and/or radiological grounds, even before pathological confirmation is forthcoming. However, this differentiation is not always possible and the clinician may sometimes be in doubt. It is particularly in cases with an acute clinical presentation that diagnosis may be difficult, even with the help of radiology and biopsy. Goligher (1971) has stated that about 10 per.cent of all patients with acute 'colitis' coming to surgery are found to have Crohn's disease on final analysis, though my experience would put the figure somewhat lower. However, there is no doubt that Crohn's disease of the large bowel may present acutely, may perforate, may cause a toxic dilatation of the colon, and may require emergency colectomy; and that the handling of these acute cases of Crohn's disease can be just as difficult and hazardous as the management of acute cases of ulcerative colitis. About 3 per cent of the St. Mark's Hospital cases have been regarded as 'unclassified', that is, those which cannot histologically be diagnosed with certainty, even on pathological examination of the whole specimen. Perhaps in a few years' time, in the light of further knowledge, it may be possible to look back and to classify these cases, or it may be found that there is yet another type of large-bowel inflammatory disease which at present is unknown.

The tendency of Crohn's disease to present with strictures of the bowel is so familiar that other possible causes of stricture may be forgotten. I have seen 2 cases with multiple colonic strictures closely resembling Crohn's disease which at laparotomy have proved to be secondary deposits from an occult primary undifferentiated carcinoma of the stomach, and a primary anaplastic carcinoma of the colon in a young patient also led to great difficulty in diagnosis. Ischaemic colitis leads to strictures in the colon, most commonly at the splenic flexure; there is usually a history of an acute attack of pain with rectal bleeding and this makes the diagnosis fairly definite. However, occasionally a stricture may be found in the colon without such a history, or in a less usual part of the colon, and then the diagnosis between ischaemic disease and Crohn's disease may be impossible. Tuberculous disease of the ileocaecal region still occurs, although in my experience it is far less common than Crohn's disease in this country at the present time. Surgical tuberculosis now is usually seen in immigrants from Asia, but recently a doctor from one of the Common Market countries was referred to St. Mark's Hospital with a diagnosis of Crohn's disease of the ileocaecal region, but after resection this proved to be a classic ileocaecal tuberculosis.

Crohn's disease may arise in, and be confined to, the sigmoid colon in some elderly patients. These are also the commonest site and age for diverticular disease so that there may be difficulties with differential diagnosis between the two conditions, which may in fact coexist. In such cases the radiological appearances may be very difficult to interpret (*Fig.* 2). Fortunately in most patients with Crohn's disease of the sigmoid colon there are inflammatory changes which can be seen on sigmoidoscopy, and anal lesions are present in about 80 per cent of cases. One should always be suspicious of any case of apparent diverticulitis associated with an anal lesion, with much oedema and granularity on sigmoidoscopy, or with much pus in the lumen of the bowel. A mucosal biopsy may be of value in such cases as it is important to make the diagnosis before undertaking surgery; patients with Crohn's disease have a greater tendency to leak at anastomoses, and a one-stage resection, as undertaken for most cases of diverticulitis, may not be suitable for a case of sigmoid Crohn's disease.

Finally on the question of diagnosis I should stress that Crohn's disease of the large bowel is very easily missed unless the possibility is constantly considered. I have in mind particularly 2 patients seen in the past year. One of these was a very neurotic lady with abdominal symptoms in whom both a barium-meal and follow-through examination and sigmoidoscopy had been quite normal. At that time she refused a barium enema and was regarded by her general practitioner as an 'irritable bowel syndrome' until a rising erythrocyte sedimentation rate and falling plasma proteins made her medical consultant insist upon a barium enema. This showed gross and extensive Crohn's disease of the large bowel. The other patient, a woman in her fifties, gave a history of vague pains in the right iliac fossa for some years, this symptom being ascribed to adhesions following a difficult appendicectomy some years previously. Recently, investigation by a rheumatologist, whom she consulted for recurrent joint pains, showed a persistently high erythrocyte sedimentation rate and a seronegative arthropathy, suggesting that her joint troubles might be secondary to a 'colitis'. Again sigmoidoscopy and a barium-meal examination were negative, but a barium enema showed two strictures in the transverse colon which proved to be typical Crohn's disease after resection (*Fig.* 3). Such cases, with little in their symptomatology or signs to suggest a lesion in the large bowel, are not uncommon, and a barium-meal and follow-through examination is a very inaccurate and inadequate procedure for diagnosing colonic disorders.

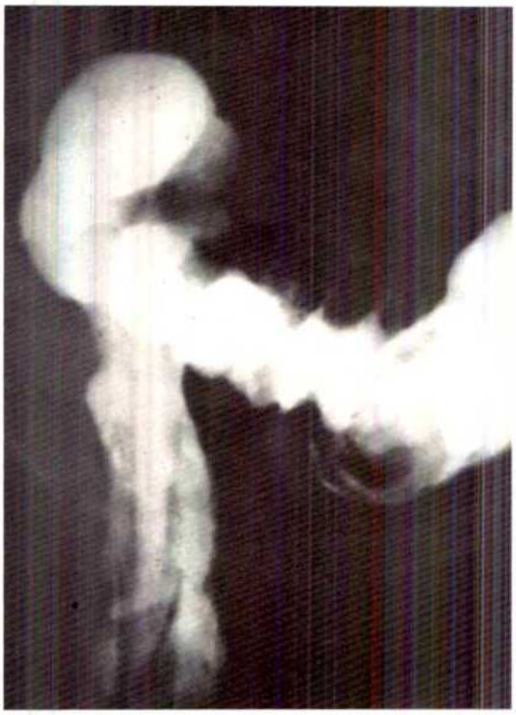

FIG. 2.—Barium-enema radiograph of the sigmoid colon affected by localized Crohn's disease. The 'spiking' shown is similar to appearances sometimes seen in diverticulitis.

Turning now to the management of patients with large-bowel Crohn's disease, I would stress that medical treatment should be attempted first unless there is a very definite indication for surgery such as marked stenosis. It is not my place to discuss medical treatment in any detail but I would like to mention the value of sulphonamides in some patients, particularly in the older age-group and those with less severe forms of the disease. Sulphathalidine alone has frequently been successful in procuring a remission lasting for some years. The value of sulphonamides, Salazopyrin, steroids, or azathioprine in the prevention of recurrence following resection for this disease is still unknown. Such information would be very valuable and controlled trials are, I believe, already under way.

In presenting some of the results of surgical treatment I would like to mention four groups of patients. First, there has been a small group with localized disease of the colon, usually presenting with a stricture in the sigmoid colon. Some of these cases have resembled or been associated with diverticular disease and have already been mentioned as presenting diagnostic difficulties. Seventeen patients with localized disease of this sort have been treated by resection and anastomosis. Many of them were elderly and some have since died of unrelated causes but 10 are alive and only 3 have had evidence of further disease, all of them with local recurrence near the site of the anastomosis. In these the operation was probably ill-chosen and the disease was more extensive than was realized at the time. However, limited surgery has been moderately successful in this group and a permanent artificial stoma has been avoided.

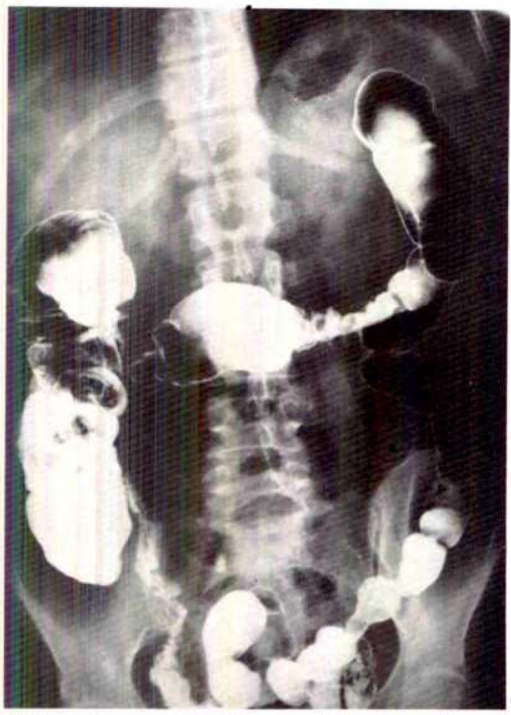

FIG. 3.—Barium-enema radiograph, showing two strictures in the transverse colon caused by Crohn's disease.

Twenty-six patients with disease apparently confined to the distal sigmoid and rectum have been treated by excision of the rectum with a terminal sigmoid colostomy. Only 1 patient has had evidence of further disease, in this case involving the rest of the colon and the terminal ileum. This distal form of the disease is rather unusual and is nearly always associated with distressing anal lesions; many of the patients have had a diverting colostomy, with very little benefit, before being referred to St. Mark's Hospital. However, this group seems to have done well after excisional surgery and they have been most rewarding patients to treat.

Total colectomy with ileorectal anastomosis has been used for patients with extensive colonic disease and a normal rectum on sigmoidoscopy and biopsy. In half of these patients the disease was confined to the large bowel, but in 13 cases there was some involvement of the terminal ileum also. Twenty-seven patients have been treated by this operation and the results are set out in *Table II*, from which it can be seen that the operation has proved somewhat disappointing. Twelve patients are well and symptom-free, 5 have active disease at the moment, which is controlled medically, 5 have required excision of the rectum for recurrence, and 5 have died, 3 of the deaths being related to surgery. All the recurrences were seen within 6 years of the operation. The success rate of the operation, therefore, is only about 50 per cent, a figure similar to those from Birmingham and Leeds (Burman, Cooke, and Williams, 1971; de Dombal, Burton, and Goligher, 1971). An analysis of the St. Mark's Hospital cases published by Baker (1971) showed that recurrence occurred both above and below the anastomosis and equally in those with or without small-bowel disease preoperatively.

Table II.—RESULTS OF COLECTOMY AND ILEORECTAL ANASTOMOSIS

Result		*No. of Patients*
Dead		5
Alive		22

	Total	27

Table III.—RESULTS OF TOTAL PROCTOCOLECTOMY

Result		*No. of Patients*
Dead		8
Alive		56
Recurrent disease	4	
	Total	64

Between 1952 and 1971 the operation of total proctocolectomy, leaving the patient with a permanent ileostomy, has been carried out in 64 patients at St. Mark's Hospital; this figure includes only those in whom all the excisional surgery was carried out there. The operation was done in one stage in 27 patients and in more than one stage in 37 patients. The results are set out in *Table III*. Eight of these patients have died: 3 as a result of surgery, 1 following persistent perineal disease, and the other 4 from unrelated causes. Of the remaining 56 patients, only 4 have had recurrent disease, that is, about 7 per cent. The shortest interval between surgery and recurrence was 10 years and the longest 17 years. It is perhaps of interest that there has been no recurrence so far in any patient treated by a one-stage proctocolectomy, but as this operation has been done mainly in the past 10 years it is not yet known if this is a significant finding. All the 4 recurrences have occurred in the terminal ileum, either at or immediately proximal to the ileostomy and there has been no case of extensive small-bowel recurrence or of a proximal skip lesion.

Comparison of the results of these two operations shows that for patients treated by total proctocolectomy the recurrence rate was less than 10 per cent, and the interval between surgery and recurrence was 10 years or more in each of the 4 cases. By contrast a recurrence rate of almost 50 per cent was seen in patients undergoing colectomy and ileorectal anastomosis, and in each of the 10 cases of recurrence the disease reappeared within 6 years of surgery. The only difference between the patients preoperatively was that those selected for ileorectal anastomosis had an apparently normal rectum on sigmoidoscopy and biopsy. There were no significant differences between the two groups in age, sex, or preoperative duration of disease. The reason for the different incidence and patterns of recurrent disease following these two procedures is not known but is obviously a field for further research and observation.

THE RESULTS OF SURGICAL TREATMENT FOR CROHN'S DISEASE

BY F. T. DE DOMBAL
UNIVERSITY DEPARTMENT OF SURGERY, GENERAL INFIRMARY, LEEDS

ANY surgeon who sets out to assess the results of his surgical intervention, whatever the disease and whatever the operative treatment, must first answer two questions. These concern the nature of the patient population under study and the nature of the assessment which the surgeon will make; in other words, which cases are to be included for assessment, and by what criteria can success and failure best be adjudged?

In Crohn's disease there are special problems involved in the assessment of results, and reference to studies in Leeds (de Dombal, Burton, and Goligher, 1971a, b) serves to illustrate both aspects. Thus, 382 patients are alleged to have been seen and treated for Crohn's disease at the General Infirmary, Leeds, yet in some 50 instances it was impossible to substantiate the diagnosis, and in only 244 of the 382 cases was it certain that the patient had undergone primary surgery in the General Infirmary. Therefore a selected (albeit well-defined) group of 244 patients was chosen for study, but it should be noted that in doing so no less than 36 per cent of the patients originally made available had to be rejected from consideration.

The criteria by which the patients were chosen for assessment have been set out elsewhere and will be discussed in detail later. However, at this juncture two points are worth making. First, the early and late results of surgery are quite different from one another, and any assessment must clearly separate these two aspects. Secondly, 'obvious' criteria for assessment (such as recurrence of disease) may not in the event be those which most reflect the patient's satisfaction with his ultimate outcome, and this point too will be dealt with in more detail in due course.

EARLY RESULTS OF SURGERY

Mortality.—There can be little doubt that the most disturbing aspect of the results of surgery for Crohn's disease is the proportion of patients who fail to survive during the early postoperative period. In the Leeds series 415 operations were performed, with a total of 24 deaths prior to the patients' discharge from hospital, an overall early mortality rate of 5·8 per cent. When one considers that many of the patients had more than one operation, the overall proportion of Leeds patients who died in the early postoperative period is no less than 7·2 per cent. Moreover, this must be seen in context of an 11·3 per cent overall related mortality for the Leeds series (which itself seems to be fairly representative in this respect, as indicated in *Fig.* 1). Thus, the majority of deaths related to Crohn's disease, its consequences, and its therapy are undoubtedly concentrated in the early postoperative period. However, as shown in *Fig.* 2, this risk is not constant, being higher after reoperations than after primary surgery and being significantly raised in elderly patients. Fortunately, as *Fig.* 2 also indicates, the overall risk is dropping (from 10 per cent in the 1940's to 3 per cent in the past decade).

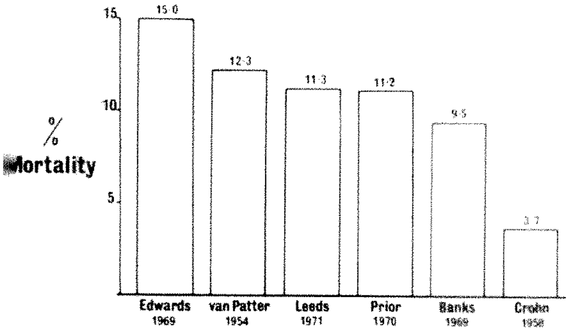

FIG. 1.—Overall mortality due to Crohn's disease in several large series.

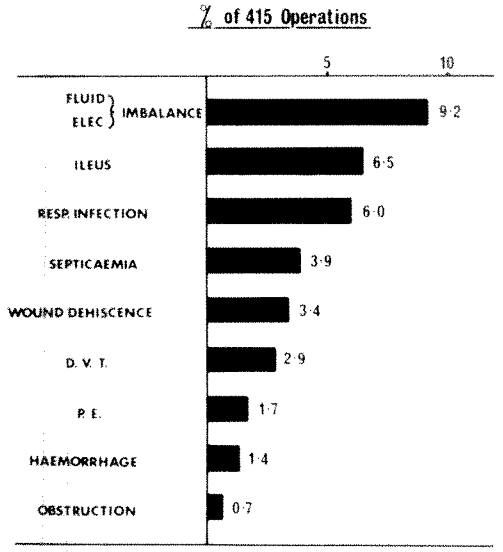

FIG. 3.—Complications in the early postoperative period.

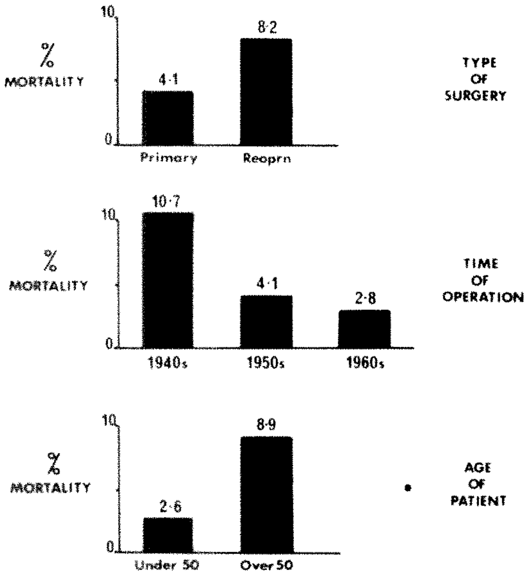

FIG. 2.—Factors affecting the overall postoperative mortality in the Leeds series.

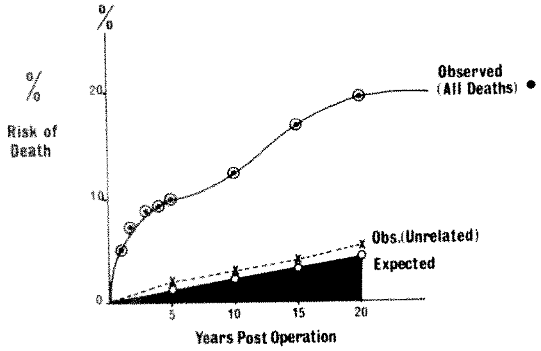

FIG. 4.—Long-term mortality after surgery for Crohn's disease.

Morbidity.—As regards the early postoperative morbidity and its various causes, the experience in Leeds is unremarkable. The various complications which may arise are listed briefly in *Fig.* 3; it is perhaps worth re-emphasizing that the patient with Crohn's disease frequently presents difficult problems in the management of fluid and electrolyte imbalance, particularly after reoperations, and that prolonged ileus is a very real risk in a proportion of patients.

LATE RESULTS OF SURGERY

Mortality.—Consideration of the long-term results of therapy for Crohn's disease must also begin with an analysis of the overall cumulative mortality, and this is shown for the Leeds series in *Fig*. 4. Quite clearly there is a small but definite mortality attributable to the disease and its therapy, since the overall death rate is greater than that which might be expected amongst the general population, yet the *unrelated* mortality is strictly comparable with that predictable from the Registrar General's (1964 figures.

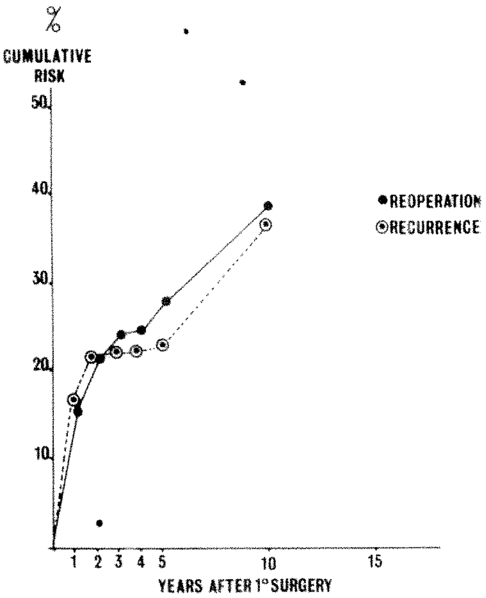

FIG. 5.—Recurrence and reoperation rates after primary surgery for Crohn's disease.

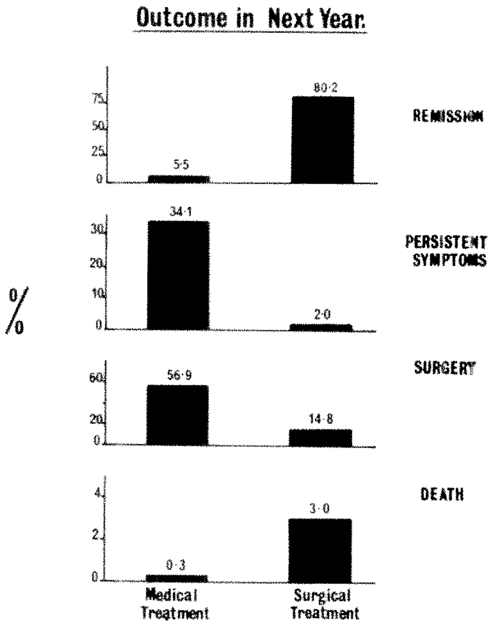

FIG. 7.—Comparison of the short-term response to conservative and operative treatments.

Reoperation and Recurrent Disease.—Thes aspects of the long-term follow-up of patients wit Crohn's disease have been dealt with at length elsewhere (de Dombal and others, 1971a, b), but it ma be helpful to make one or two additional point First, reoperation and recurrent disease are undoubtedly related in that most reoperations ar performed on account of recurrent disease, as show in *Fig*. 5. Secondly, both the curves in *Fig*. 5 ar biphasic, and this points to the possibility of mor than one type of recurrence—a hypothesis which ha already been developed elsewhere at some lengt Finally, the Leeds experience is probably reasonabl representative, as demonstrated by consideration c the overall recurrence rates from a number of larg series (*Fig*. 6).

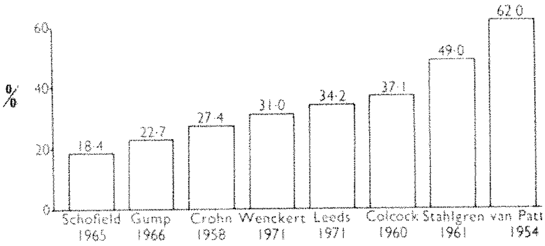

FIG. 6.—Overall recurrence rates from a number of large series.

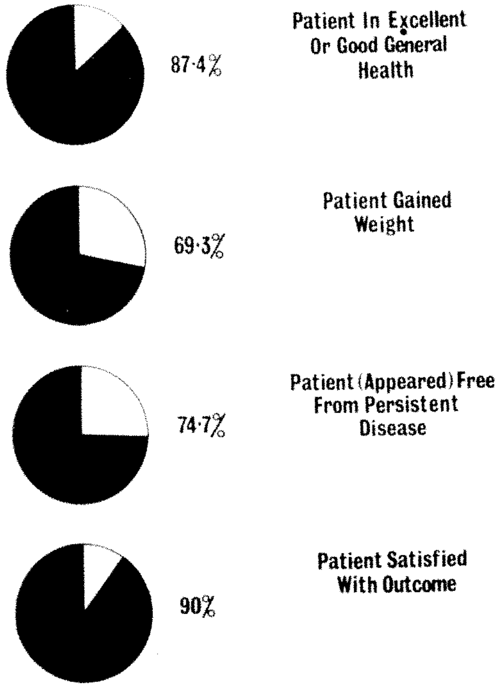

FIG. 8.—Overall status of the surviving patients at the time of the review.

Symptomatic Course.—This can only proper be assessed if one compares the symptomatic cour following surgery with that of patients on long-ter conservative therapy. An assessment of the course he initial year is shown in *Fig.* 7, which illustrates two main features. First, the mortality after surgical treatment is much higher than that on conservative management alone (3·0 versus 0·3 per cent). This presumably reflects a situation in which the more severe the symptoms are, the more likely the patient is to undergo surgical treatment. Secondly, as regards the symptomatic outcome, *Fig.* 7 emphasizes the paucity of response to conservative management, so that only 5 per cent of patients on continuous onservative management actually achieved a full emission of symptoms. Conversely, no less than 80 per cent of the patients operated upon during their initial attack of Crohn's disease spent at least the next year in full clinical remission. Moreover, as has been shown elsewhere (de Dombal and others, 1971b), hese general trends persist throughout the course of he patients' illness, in that years on conservative management alone are vastly more likely to be marred by symptoms of Crohn's disease than are years following surgical intervention.

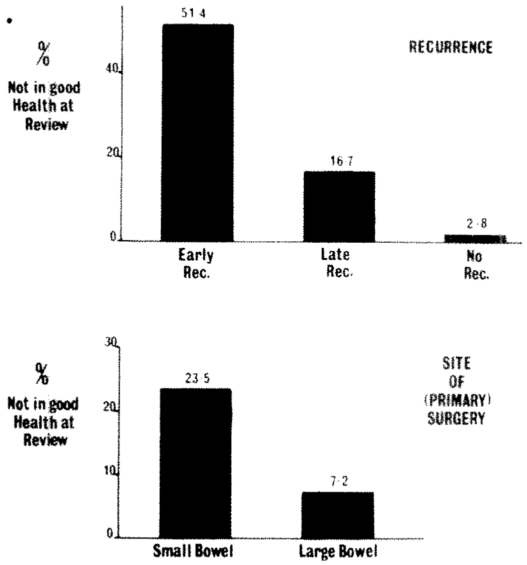

FIG. 9.—Factors modifying the status of the survivors at review.

STATUS OF PATIENTS AT REVIEW

The status of the patients at the time of their review in Leeds was really very much better than had been imagined. As indicated in *Fig.* 8, the vast majority of surviving patients were in acceptable general health, had maintained or gained weight, were apparently free from persistent disease, and were broadly satisfied with their treatment and its outcome. Two factors modify this picture (*Fig.* 9), namely whether or not the patient had a recurrence and if so the timing of that recurrence), and also the primary site of surgical intervention. Surprisingly, he length of follow-up between the time of primary surgery and the review in 1968 did not seem to affect he status at review in any major way (*Fig.* 10). This would seem to give grounds for hope that the reasonably good short-term results obtained so far will not deteriorate too much with the passage of time.

CONCLUSIONS AND SUMMARY

Thus, what might be termed the 'central equation' or the 'central dilemma' in the management of Crohn's disease and in the consideration of the role of surgery within that management is arrived at. On the one hand, conservative management is relatively safe, whereas surgery in the 1960's has been followed by an immediate risk to life of approximately 3 per cent (higher in old people and after multiple operations). On the other hand, long-term conservative management does little to alleviate symptoms and surgery is notably successful in this respect. Are the individual patient's symptoms sufficiently disabling to warrant acceptance of an immediate risk to life of around 3 per cent? On the answer to that question must depend the decision to offer or to withhold operative treatment.

SYMPOSIUM ON THROMBO-EMBOLISM—CURRENT MANAGEMENT

THE DIAGNOSIS OF DEEP-VEIN THROMBOSIS

BY DAVID NEGUS
DEPARTMENT OF SURGERY, ST. THOMAS'S HOSPITAL MEDICAL SCHOOL, LONDON

DEEP-VEIN thrombosis is a common complication of surgical operation (Sevitt and Gallagher, 1959; Flanc, Kakkar, and Clarke, 1968; Negus, Pinto, LeQuesne, Brown, and Chapman, 1968) and of major illness (Maurer, Wray, and Shillingford, 1971), and pulmonary embolism is responsible for many deaths each year (Kemble, 1971). It is well recognized that many small calf-vein thromboses give rise to no symptoms or signs (Kakkar, 1969; Negus, Pinto, and Brown, 1969b). More importantly, extensive femoral or iliac thromboses are also frequently 'silent' (Mavor and Galloway, 1969; Evans, 1971).

The importance of early and accurate diagnosis of this potentially dangerous condition is reflected in the number of ingenious attempts which have been devised to improve the situation (*Table I*). Some of these, such as the measurement of platelet adhesiveness, have proved unreliable, and others, for example the measurement of fibrin-degradation products, are at present too complicated for daily clinical use.

Table I.—METHODS OF DIAGNOSING DEEP-VEIN THROMBOSIS

AUTHOR	METHOD	RELIABILITY
Bauer (1940)	Phlebography	Reliable
Atkins and Hawkins (1965)	^{125}I-fibrinogen	Reliable
Bygdeman, Eliasson, and Johnson (1966) Hume (1966) Negus, Pinto, and Brown (1969a)	Platelet adhesiveness	Unreliable
Lane (1967)	Infra-red thermography	Unproved
Sigel and others (1968)	Doppler ultrasound	Reliable
Mullick and others (1970)	Limb impedance	Unproved
Fletcher, Alkjaersig, O'Brien, and Tulevski (1970)	Fibrin-degradation products	Reliable, complex

Impedance phlebography is a recent development with encouraging possibilities (Mullick, Wheeler, and Songster, 1970). The method depends on the patient's ability to take a deep breath and to hold it for 5 seconds; this changes the venous volume and electrical conductivity of the limb, and the difficulty some patients may find in doing this perhaps accounts for the poor accuracy of the method (53·5 per cent) in one series (Dmochowski, Adams, and Couch, 1972). Impedance phlebography can only detect thromboses in the major veins of the leg and pelvis (Wheeler, Pearson, O'Connell, and Mullick, 1972), and at present would appear to have no advantages over the Doppler ultrasound technique.

The present paper is confined to a description of the three proved methods currently available for the diagnosis of deep-vein thrombosis: phlebography, Doppler ultrasound, and ^{125}I-fibrinogen uptake. Th details of these techniques have been reported s often recently that there is no need to repeat then and I will concentrate on describing the advantag and limitations of each and on their relative values i clinical practice and research.

PHLEBOGRAPHY

Phlebography is the most useful single diagnosti method for the investigation of suspected deep-vei

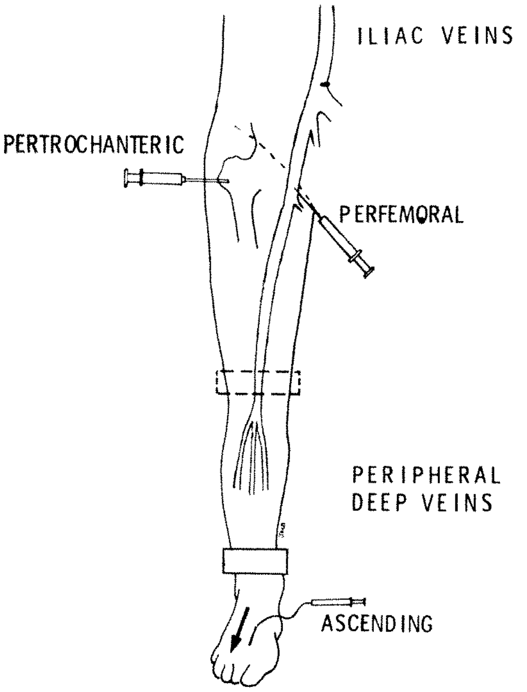

FIG. 1.—Phlebography in the diagnosis of deep-vein thrombosis. The above-knee cuff is removed for delineation of the femoral and iliac veins.

thrombosis. Delineation of the peripheral deep vei is performed by retrograde injection of contra medium into a dorsal foot vein, the superficial vei being occluded by an ankle cuff. The investigation most satisfactorily performed with help from an imag intensifier. With the exception of some of th intermuscular veins, good views of the deep veins an of the calf and thigh are easily obtained, and wit suitable patient tilting and calf compression the ilia veins can also be examined by this technique (L

Thomas, 1971). More precise delineation of the iliac veins and inferior vena cava is achieved by iliac phlebography, usually by the pertrochanteric route (Lea Thomas, 1969), as direct femoral puncture is often impossible in the presence of thrombus (*Fig.* 1).

A phlebogram not only shows the extent of thrombus formation but also indicates its fixity to the vein wall—a point of extreme importance in the management of pulmonary embolism or where surgical thrombectomy or fibrinolytic therapy is being considered. Loose, potentially removable thrombus produces a 'ground-glass' type of shadow and contrast medium can be seen between the thrombus and the vein wall (*Fig.* 2). Older, fixed thrombus results in radiological disappearance of the affected vein, and this is usually accompanied by the presence of dilated collateral veins (*Fig.* 3).

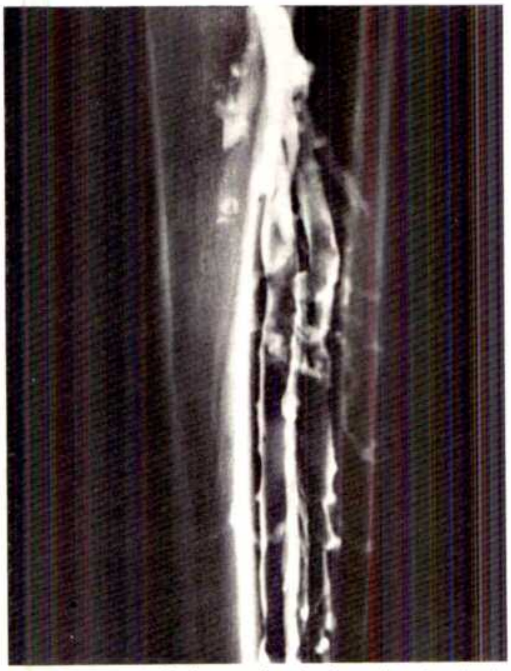

FIG. 2.—Peripheral phlebogram showing loose thrombus in the calf veins.

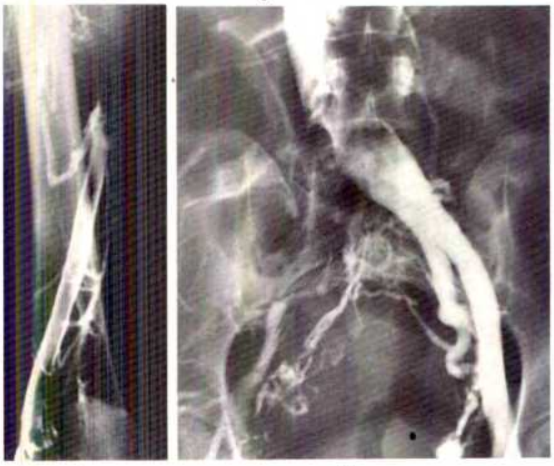
Phlebography demands no more than the normal resources of an average radiological department with, in addition, the interest and time of a radiologist. Of these simple requirements, time is usually the least readily obtainable.

The disadvantage of phlebography is that there must be some indication for its use, and, as is well known, many deep-vein thromboses are completely 'silent'. Some sort of screening technique is therefore advisable, and the two such techniques presently available are Doppler ultrasound (Strandness, Schultz, Sumner, and Rushmer, 1967; Sigel, Popsky, Wagner, Boland, Mapp, and Feigl, 1968) and the ^{125}I-fibrinogen technique (Hobbs and Davies, 1960; Atkins and Hawkins, 1965). Both methods have been established as accurate by comparison with phlebography (Flanc and others, 1968; Negus and others, 1968; Evans and Cockett, 1969; Yao, Gourmos, and Hobbs, 1972) and the technical details of each have recently been described (Evans and Negus, 1971).

DOPPLER ULTRASOUND TECHNIQUE

Doppler ultrasound, or, more properly, the transcutaneous Doppler ultrasound flow-detection method,* detects changes in flow velocity, such changes being electronically converted either into sound or into a graphic record. Patency of a vein is indicated by a change in flow velocity being produced under the flow probe by a distant stimulus. With the probe placed over the common femoral vein the necessary increase in flow velocity is effected either by squeezing the leg distal to the probe, which increases femoral vein flow and produces a loud noise from the apparatus, or by changes in respiration, such as the Valsalva manœuvre, which alter flow velocity in the inferior vena cava and iliac veins and result in a wind-like roaring. Venous obstruction prevents the transmission of flow changes and therefore no noise is produced by the apparatus (*Fig.* 4).



A B

FIG. 3.—A, Peripheral phlebogram of a 23-year-old woman. The lower third of the superficial femoral vein contains loose thrombus and above this the lumen is occluded by adherent thrombus. B, Pertrochanteric iliac phlebogram of the same patient showing occlusive thrombus in the right external and common iliac vein.

Doppler ultrasound has the great merits of simplicity, speed, and inexpensiveness, and with a little training and experience can be safely and usefully employed by medical students and technicians. The technique is not capable of detecting thromboses confined to the calf, but this disadvantage is less serious than it may first seem as calf thrombi, though by far the most common of all deep-vein thromboses, are unlikely to produce emboli of significant size unless they propagate to the popliteal vein (Evans, 1971).

Doppler ultrasound is used at St. Thomas's Hospital for twice-weekly examinations of the legs and iliac veins of patients recovering from major surgery until the patient is fully ambulant. The results of similar ward surveys have been reported (Evans, 1971; McIlroy, 1972).

---

* The apparatus in most general use is the Sonicaid D. 205.

The method is also useful for the rapid investigation of patients with suspected deep-vein thrombosis and it can be used to decide on the necessity for phlebography. For instance, when there are unequivocal signs of calf-vein thrombosis and Doppler ultrasound shows no evidence of propagation to the popliteal vein and no femoral or iliac vein obstruction, treatment with anticoagulants can be started without further investigation by phlebography. Monitoring by Doppler ultrasound must be continued in the early stages of such treatment.

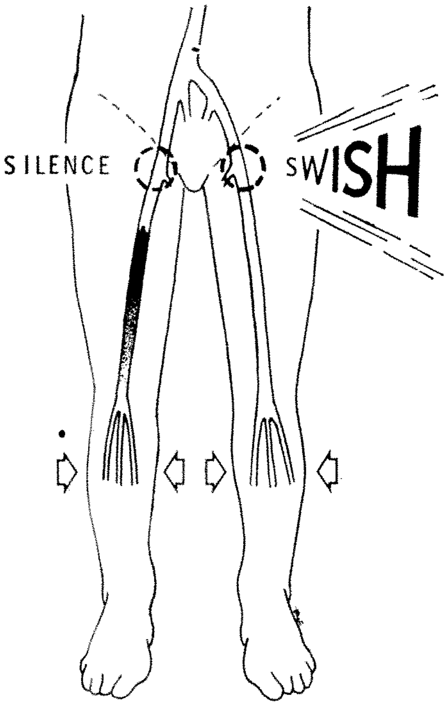


FIG. 4.—Diagram showing the principle of Doppler ultrasound detection of venous obstruction.

^{125}I-FIBRINOGEN-UPTAKE TECHNIQUE

The ^{125}I-fibrinogen-uptake technique depends on the incorporation of human-serum fibrinogen, obtained from a small pool of hepatitis-free donors and labelled with ^{125}Iodine,* into a forming thrombus, where it can subsequently be detected by an external scintillation counter. ^{125}I-fibrinogen, 50–100 µc., is injected intravenously after blocking thyroid uptake with oral inorganic iodide, and the measurement of radioactivity is subsequently made either with a scaler or with a ratemeter.† Details of the technique and of the criteria for the diagnosis of thrombosis have previously been reported (Negus and others, 1968; Evans and Negus, 1971) (*Figs.* 5 and 6). The method will accurately detect small thrombi in the lower leg and thigh, but it cannot be used in the presence of healing wounds or in the groin or abdomen where thrombus formation not infrequently occurs independently of the calf veins (Evans and Negus, 1971).

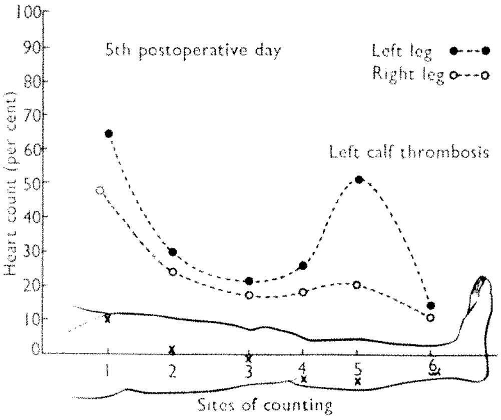

FIG. 6.—^{125}I-labelled fibrinogen detection of venous thrombosis in the left leg of a 63-year-old woman.

Fibrinogen uptake is primarily a method for the prospective detection of forming thrombi and is very suitable for patient screening and for research. The method has produced much information about the natural history of lower-leg deep-vein thromboses which are common, occurring in about 28 per cent of middle-aged and elderly patients undergoing major surgical operation (Browse and Negus, 1970), and which are now known to appear early in the post-operative period (Flanc and others, 1968; Negus and others, 1968; Kakkar, 1969; Negus and others, 1969b). Many trials of means of preventing deep-vein thrombosis have used fibrinogen uptake as the method of detection (*Table II*).

---

* Obtainable from the Radiochemical Centre, U.K. Atomic Energy Authority, Amersham, Bucks.

† A scaler is preferable for research; a ratemeter is suitable for routine clinical use. A suitable portable ratemeter is the Isotope Localization Monitor, 235, D. A. Pitman Ltd.

Fibrinogen uptake also has a useful place in routine clinical practice, being an accurate method of screening high-risk patients undergoing major surgical operation. The precise definition of high risk is difficult, but it may broadly be said that the risk of thrombosis increases with age; other conditions carrying a high risk include a past history of deep-vein thrombosis, obesity, malignant disease, thoracotomy, splenectomy, hip operation, and retropubic as opposed to transurethral prostatectomy.

The method is inadvisable in young or pregnant patients. It cannot detect groin or iliac thromboses and should therefore always be used in conjunction with Doppler ultrasound. The combination of the ^{125}I-fibrinogen and Doppler ultrasound techniques can also be used for the diagnosis of the suspected case if phlebography is not available. It takes at least 6 hours from the intravenous injection to obtain a result (Nanson, Palko, Dick, and Fedoruk, 1965). Thrombi more than 6 or 7 days old may be undetectable and the method is unreliable in the presence of much oedema (Browse, Clapham, Croft, Jones, Lea Thomas, and Williams, 1971). These disadvantages make phlebography preferable in most patients with suspected deep-vein thrombosis.

Table II.—THE PROPHYLAXIS OF DEEP-VEIN THROMBOSIS: TRIALS USING ^{125}I-FIBRINOGEN

AUTHOR	METHOD	EFFECTIVENESS
Rosengarten and Laird (1971)	Leg elevation	Ineffective
Rosengarten, Laird, Jeyasingh, and Martin (1970)	Elastic stocking	Ineffective
Browse and Negus (1970)	Galvanic calf stimulation	Effective
Sabri, Roberts, and Cotton (1971a)	Foot pedal	Effective
Hills, Pflug, Jeyasingh, Boardman, and Calnan (1972)	Intermittent calf compression	Effective
Sabri, Roberts, and Cotton (1971b)	Intermittent calf compression	Effective
Lambie, Barber, Dhall, and Matherson (1970)	Dextran	Effective
Kakkar, Field, Nicolaides, Flute, Wessler, and Yen (1971)	Heparin (low doses)	Effective
Williams (1971)	Heparin (low doses)	Effective

Table III.—THE DIAGNOSIS OF DEEP-VEIN THROMBOSIS

Subject	*Investigation*	
Routine ward screening	Doppler ultrasound	
Selected patient screening and research	^{125}I-fibrinogen + Doppler ultrasound	
The suspected case Presentation:—	*Rapid preliminary*	*Final*
Calf tenderness ± swelling	Doppler ultrasound	Phlebography or ^{125}I-fibrinogen
Acute white leg	—	Phlebography
Chronic leg swelling	Doppler ultrasound	Phlebography Lymphography
Pulmonary embolism	Doppler ultrasound	Phlebography
Collapse ? massive pulmonary embolism ? myocardial infarct	Doppler ultrasound	Electrocardiogram and chest radiograph then phlebography

CONCLUSIONS

These are the methods of detecting deep-vein thrombosis presently available. The indications for each are summarized in *Table III*, where it will be seen that Doppler ultrasound is generally used for rapid preliminary investigation and for routine ward screening to indicate the presence or absence of femoral or iliac thrombus. Phlebography is generally used for definitive diagnosis. ^{125}I-fibrinogen is useful in research and in screening high-risk patients, and in the diagnosis of suspected calf or femoral thrombosis it can be substituted for phlebography if the latter is unavailable, provided that its limitations when used in this way are clearly understood (*Fig*. 7). It should be used in conjunction with Doppler ultrasound.

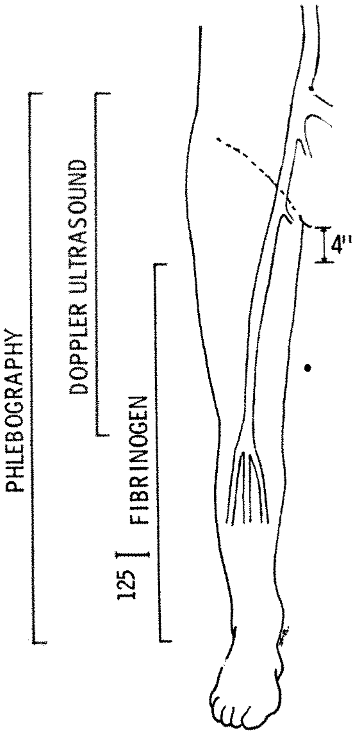

FIG. 7.—The venous drainage of the lower limb showing the segments in which each method of diagnosis is accurate.

In the establishment of diagnostic facilities for a clinical unit the order of priority should be:—

1. Phlebography.
2. Doppler ultrasound.
3. If there are then sufficient funds and personnel available the means of performing the ^{125}I-fibrinogen uptake technique should be obtained.

The research worker would do well to put his priorities in the reverse order.

Acknowledgements.—I am grateful to Dr. M. Lea Thomas for allowing me to reproduce radiographs, and to Mrs. E. K. H. Miles for her secretarial help. The illustrations have been provided by Mr. J. Bamfield, Medical Chartist, and the photographs by Mr. T. Brandon, Department of Clinical Photography, St. Thomas's Hospital.

CONSERVATIVE MANAGEMENT OF THROMBO-EMBOLISM

BY P. T. FLUTE
KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, LONDON

THIS communication is concerned with the use of drugs for the treatment of established thrombosis of the deep veins of the leg. Other well-tried principles of conservative management, such as firm external support to the legs, active leg exercises, elevation of the foot of the bed, and early ambulation, should not, however, be neglected.

The use of anticoagulant or thrombolytic drugs, at any level of therapeutic effect, entails a risk of bleeding. This risk rises sharply if the patient's vascular system is damaged, if there is any other reason for impaired haemostasis, for example renal failure or liver failure, or if the administration of the drug departs from the accepted standards of control. Close clinical supervision of the patient is the most important form of control. Overt bleeding can sometimes be tolerated, but any suspicion of concealed bleeding, for example retroperitoneal haemorrhage, indicates the need for modification of the treatment whatever the results of laboratory tests.

With the exception of massive thrombosis, phlegmasia caerulea dolens or phelgmasia alba dolens, which is not amenable to any form of conservative treatment, clinical diagnosis is unreliable. The usual signs of thrombosis may be absent, and even when they are elicited the presence of a thrombus cannot be assumed with any confidence (Nicolaides, Kakkar, Field, and Renney, 1971). In a study of 247 patients believed to have deep-vein thrombosis ascending phlebography showed that 35 per cent had normal radiographic appearances of the whole venous drainage of both legs, including the iliac veins (Kakkar, 1972). Dependence on clinical signs alone must mean that some patients who need treatment will not receive it, while for others it will be superfluous. Fortunately, this dilemma is resolved by the known prophylactic effect of the oral anticoagulants (Sevitt and Gallagher, 959). For patients in whom there are suggestive clinical signs at least a high risk of thrombosis may be assumed, and this is enough to justify the use of these drugs until the risk is thought to have passed. The oral anticoagulants are selected for this purpose in preference to other prophylactic agents since clinical experience suggests that they may hasten the resolution of established thrombi and reduce the incidence of complications, pulmonary embolism, and the post-phlebitic syndrome. However, this belief has never been satisfactorily tested by a controlled trial.

There are many patients in whom oral anticoagulants will fail to prevent extension of a thrombus or the occurrence of pulmonary embolism. Whenever possible, objective diagnosis of the thrombosis should be obtained, as has already been discussed by Mr. Negus (*see* p. 830). When the age, site, and the size of the thrombus are known it is possible to formulate a more ambitious policy of treatment, knowing that the greater risks of bleeding are acceptable for those patients whose life is imperilled by a thrombus in the veins above the knee. Considerable evidence now shows that a thrombus in the popliteal or any proximal vein is the type which gives rise to massive pulmonary embolism (Sevitt and Gallagher, 1961; Kakkar, Howe, Flanc, and Clarke, 1969; Mavor and Galloway, 1969). The alternatives to be considered here (to be used only with such objective diagnosis) are a continuous infusion of heparin, ancrod (Arvin, Twyford Laboratories Ltd.), or streptokinase. Treatment can be continued until objective assessment shows that the maximum benefit has been obtained; new streptokinase antibodies are likely to prevent its use for longer than 7 days. Urokinase is not yet generally available for the treatment of deep-vein thrombosis.

Oral Anticoagulants.—The risk of bleeding has been reduced by recent advances in the study of the pharmacology and control of the oral anticoagulants, which decrease the liver synthesis of the vitamin-K-dependent clotting factors. The risks of hypersensitivity to indanediones, including phenindione, are now recognized, and the coumarin derivatives such as Warfarin are therefore preferred (Douglas, 1971). There is a greater awareness of the possibility of interaction with a multiplicity of other drugs (Koch-Weser and Sellers, 1971). Those interactions which occur in hospital are usually evident from laboratory control. Out-patients must be warned against self-medication and alcoholic intoxication. It is also necessary to guard against the more insidious risk of withdrawal of certain drugs, especially the barbiturates, with the consequent decay of the new enzymes which these drugs have induced in the liver. These enzymes increase drug metabolism and as they decay (often 2–3 weeks after stopping the sedatives when leaving hospital) the metabolism of Warfarin slows down. Consequently there is an increased anticoagulant effect and a real risk of bleeding. This can be anticipated by a reduction of the anticoagulant dose or, preferably, by avoiding the known enzyme-inducing drugs in patients treated with anticoagulants.

The great variations in laboratory control as practised in different hospitals have been eliminated by the introduction of the British Comparative Thromboplastin Reagent (Poller, 1969) for the one-stage prothrombin time. All hospitals can now refer their results to a British Comparative Ratio of patient-to-control prothrombin time. When this ratio lies between 1·8 and 3·0 an effect has been achieved which corresponds to a value for the Thrombotest, the alternative standardized reagent, of 6–10 per cent. Sevitt and Innes (1964) showed the latter value to be more effective in prophylaxis than values of 10–20 per cent. Since any lower level frequently causes bleeding this is a relatively well-defined therapeutic range for laboratory control.

Heparin.—This acidic mucopolysaccharide directly inhibits the formation and action of thrombin. Many clotting tests, including the clotting time, partial thromboplastin time, and thrombin time, are prolonged by heparin, but there is little correlation between them (Pitney, Pettit, and Armstrong, 1970). It is also possible to express the results as the amount of protamine needed to return the test to normal (O'Shea, Flute, and Pannell, 1971). No therapeutic range has been defined. Empirically, it seems desirable to modify the dose of heparin to produce a change in the test chosen by the laboratory. Bleeding may occur at any level but seems more common if the ratio of patients-to-control thrombin time exceeds 10. Immediate neutralization of the heparin effect is achieved by intravenous protamine.

Ancrod.—This fraction of the venom of the Malayan pit viper removes A-fibrinopeptides from fibrinogen without directly affecting coagulation enzymes or platelets. The resulting molecules spontaneously polymerize to form 'micro-clots' which are rapidly removed from the circulation by reticulo-endothelial cells, leaving a low-plasma fibrinogen. This novel anticoagulant action has the additional merit of reducing plasma viscosity. Control is by measurement of the plasma fibrinogen or by a simple clot-observation test (Pitney, Bray, Holt, and Bolton, 1969). The effects can be reversed by an anti-venom, which unfortunately carries a risk of hypersensitivity reactions since it is prepared in animals, and by the transfusion of fibrinogen concentrates, which may transfer virus hepatitis.

Streptokinase.—This purified exotoxin of haemolytic streptococci combines with human plasminogen to form an activator which converts additional plasminogen to plasmin. This enzyme has a direct thrombolytic effect and the fibrinogen/fibrin degradation products (F.D.P.) resulting from its action have complex anticoagulant properties (Kowalski, 1968). Among the drugs considered, only streptokinase has this combined thrombolytic and anticoagulant effect.

An initial dose of 250,000–500,000 U. is given intravenously in the first 30 minutes. This is sufficient to neutralize circulating anti-streptokinase antibodies — a legacy of previous streptococcal infections—in the majority of patients and to leave an excess of streptokinase which will convert much of the circulating plasminogen to plasmin (Verstraete, Vermylen, Amery, and Vermylen, 1966; Kakkar, Flanc, Howe, O'Shea, and Flute 1969; Amery, Deloof, Vermylen, and Verstraete, 1970). Before the plasmin is fully neutralized by circulating antiplasmins it will begin to digest many of the plasma proteins. Bleeding may follow the resulting decrease of clotting factors, especially fibrinogen, and the consequent liberation of F.D.P. However, if a continuous maintenance infusion of 100,000–150,000 U. hourly immediately follows the initial dose of streptokinase the only source of plasminogen is that which is freshly synthesized and since this is a slow process the greatest danger is limited to the first few hours when significant amounts of plasminogen are available. Laboratory control is carried out by using the thrombin time, which is prolonged either by a decrease in the fibrinogen or an increase in the F.D.P. A very long time is to be expected in the first few hours and indicates that the initial dose has been effective; after 6–12 hours it should return to normal. After this, a ratio of patient-to-control thrombin time of 3·0 or more suggests that blood-plasminogen levels are increasing with resulting formation of plasmin and F.D.P. in excess, and a renewed risk of bleeding. This indicates the need to check the delivery of the maintenance dose of streptokinase; it will usually be found that this has decreased, often for technical reasons, for example obstruction of the intravenous drip. The drug is best given by a reliable mechanical delivery device.

It is important that circulating antibody is neutralized by the initial dose. Patients with recent streptococcal infection or those who have received streptokinase previously should have the level of antibody measured before infusion (Flute, 1964). Safety depends on maintaining a low concentration of blood-plasminogen. It may become necessary to reverse the effects of streptokinase rapidly because of bleeding or because urgent surgery is required. An inhibitor of fibrinolysis, for example epsilon aminocaproic acid, should be given before the transfusion of blood or blood-products containing plasminogen. With this proviso even major thoracic surgery is possible within an hour of ending a streptokinase infusion. Streptokinase is rapidly cleared from the blood and no inhibitor is needed at the end of a successful infusion, although this should be followed by oral anticoagulants for 6–8 weeks to prevent rethrombosis. Heparin can be used, beginning 6 hours after the end of infusion, to cover the period while oral anticoagulants develop their effect.

THE CHOICE OF THERAPY

When a thrombus is extending or is in the popliteal or a proximal vein the risk to life justifies active treatment unless one of the well-known contra-indications makes any form of drug therapy unacceptable. Of the alternatives mentioned, only streptokinase has the direct thrombolytic effect which offers the greatest chance of rapid dissolution of thrombus, perhaps with preservation of function of the venous values (Kakkar, Howe, Laws, and Flanc, 1969). Streptokinase is more likely to be completely effectiv if the thrombus is less than 96 hours' duration Against this must be set the risk of bleeding and o allergic reactions. Older thrombi completely occludin the lumen in limbs where there is a well-develope collateral circulation are less likely to achieve complet dissolution with streptokinase, and perhaps are bes treated by continuous heparin infusion for 3–4 day and oral anticoagulants for 6 months, until th maximum possible recanalization of the vein obtained. The response to any form of treatmen should be measured objectively, usually by repeate phlebograms.

CONCLUSION

Any policy must be tentative and will requir modification as knowledge of the natural history o thrombosis advances. At present clinical suspicion o deep-vein thrombosis may be held to justify only ora anticoagulants and local measures to relieve symptom If a precise anatomical diagnosis shows a thrombu in the popliteal vein or above a difficult choice mus be made between treatment with heparin, ancrod streptokinase, or surgery.

THE DIAGNOSIS AND MANAGEMENT OF MASSIVE PULMONARY EMBOLISM

BY G. A. H. MILLER
BROMPTON HOSPITAL, FULHAM ROAD, LONDON

N a group of more than 50 patients seen at the Brompton Hospital, London, all of whom had isolated acute massive pulmonary embolism, it has been possible to define the haemodynamic disturbance, and hence the presenting symptoms and signs, resulting from acute obstruction to right ventriular outflow occurring as an isolated disturbance. Patients are included only if the embolism was of less than 48 hours' duration and its presence and severity were proved by pulmonary arteriography, embolectomy, or both. No patient is included in whom there was pre-existing cardiorespiratory disease.

DIAGNOSIS

The symptoms and signs of isolated, acute, massive, pulmonary embolism are (1) a sudden reduction in the cardiac output, (2) acute right entricular failure, and (3) disturbance of pulmonary entilation and perfusion (Gorham, 1961; Paneth, 966; Dalen and Dexter, 1969; Sutton, Honey, nd Gibson, 1969; Miller and Sutton, 1970). The sudden reduction in cardiac output results in the most common presentation (80 per cent of patients): sudden faintness or collapse, with frank circulatory arrest occurring in 22 per cent. The clinical manifestation of this low output state is a sinus tachycardia 90 per cent of patients) with a small sharp pulse, systemic hypotension, and signs of peripheral constriction with poor tissue perfusion (low urine flow, disturbed cerebration, etc.). The other cardinal presenting feature—sudden onset dyspnoea (74 per ent of patients)—may result from a low cardiac output ('air hunger') as well as disturbed pulmonary entilation and perfusion. It is an important clue to the diagnosis that these patients are not orthopnoeic but prefer to lie flat, as might be expected when ardiac output is critically dependent on filling pressure and in contradistinction to the orthopnoea f pulmonary *venous* hypertension (e.g., myocardial nfarction). Other presenting symptoms include central chest pain (34 per cent) and occasional pleurisy and haemoptysis, though these signs of pulmonary infarction are more commonly present as result of small premonitory emboli prior to the onset of massive embolism.

Acute right ventricular failure is detected clinically by a gallop rhythm best heard at the left sternal edge 87 per cent of patients) and elevation of the central enous pressure (79 per cent). These signs appear to be time dependent and may be absent in a patient een between 24 and 48 hours after the acute event ither as a result of some spontaneous resolution or because of some adaptation to massive embolism. The acutely failing right ventricle cannot generate a high pressure to overcome the obstruction and the physical signs of isolated acute embolism are *not* those of pulmonary hypertension.

Disturbance of pulmonary ventilation and perfusion leads to central cyanosis (detected in 62 per cent of patients). Occasionally severe arterial desaturation may be due to right-to-left interatrial shunting via the foramen ovale.

INVESTIGATION

Apart from pulmonary arteriography the electrocardiogram (E.C.G.) and chest radiograph provide the most useful information in massive pulmonary embolism. The E.C.G. abnormalities most commonly found reflect abnormalities of right ventricular conduction or repolarization; these abnormalities include the classic $S_1Q_3T_3$ pattern with or without T-wave inversion in leads V1–V3 or V4 (McGinn and White, 1935; Cutforth and Oram, 1958) and right bundle branch block. These changes may be evanescent. Occasionally left-sided E.C.G. changes occur (Medd and McBrien, 1962) and in some cases the E.C.G. may be normal despite massive pulmonary embolism.

The plain chest radiograph may appear deceptively normal but on close inspection oligaemia of the affected zones is an almost invariable finding (Westermark, 1938). Other radiographic abnormalities include an elevated dome of the diaphragm, infarct shadows, and a 'plump' hilar shadow. Radiologically detectable enlargement of the main pulmonary trunk is not a feature of acute massive pulmonary embolism without previous cardiorespiratory disease (Kerr, Simon, and Sutton, 1971).

Definitive diagnosis is provided by pulmonary arteriography. While this procedure cannot be without risk in such critically ill patients we have performed this investigation in well over 40 such patients without mortality. The volume of contrast medium must, however, be reduced to 0·75 or 0·5 ml. per kg. body-weight to avoid peripheral vasodilatation, which can lead to a profound, but transient, hypotension in patients who have a fixed and low cardiac output.

TREATMENT

Since duration and severity of embolism and the presence of coexisting cardiorespiratory disease affect the prognosis and rate of resolution of pulmonary emboli, the present series of patients in whom both the duration and the severity of embolism were known formed an ideal group in which different treatment régimes could be assessed. Three approaches to treatment have been employed: emergency pulmonary embolectomy on the one hand and medical treatment with anticoagulant (heparin) or thrombolytic (streptokinase) therapy on the other. Since none of the patients (most of whom were referred from other centres) was seen within 2 hours of embolism I have little personal experience of the initial resuscitation or of Trendelenburg or inflow occlusion embolectomy which is the only treatment available when resuscitation fails. Cross and Mowlem (1967) have reported the collective experience of 40 surgeons working in the United States. As might be expected, Trendelenburg or inflow occlusion embolectomy carried a high mortality (87 per cent) whereas by-pass embolectomy was accompanied by a 57 per cent mortality with a further 11 per cent late deaths. The patients included in the present study, having survived for 2 hours or more, were obviously a relatively good-risk group and our experience with embolectomy has been more favourable. By-pass embolectomy has been associated with an overall mortality of 23 per cent and only 1 out of 13 patients so treated has died since 1968; this patient was moribund and having cardiac massage on arrival a the operating theatre. The occurrence of cardia arrest has carried a bad prognosis; among those wit such a history the mortality has been 66 per cer whereas no patient has died following embolectom when the history did not include an episode of cardia arrest (*Fig.* 1).

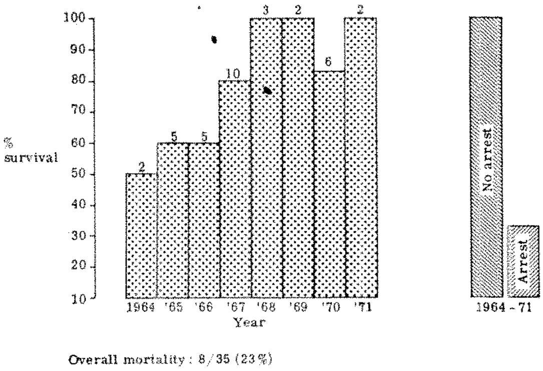

FIG. 1.—*Left-hand panel*, percentage survival following pulmonary embolectomy in patients with isolated, acute, massive pulmonary embolism. Numbers indicate the number of patients undergoing embolectomy each year. *Right-hand panel*, percentage survival for all the patients following embolectomy. For those patients in whom the history included an episode of cardiac arrest the mortality was 66 per cent; where there was no such history the survival rate is 100 per cent. (*I would like to acknowledge the help of Mr. M. Paneth, F.R.C.S., and Mr. S. C. Lennox, F.R.C.S., whose results for pulmonary embolism are presented here.*)

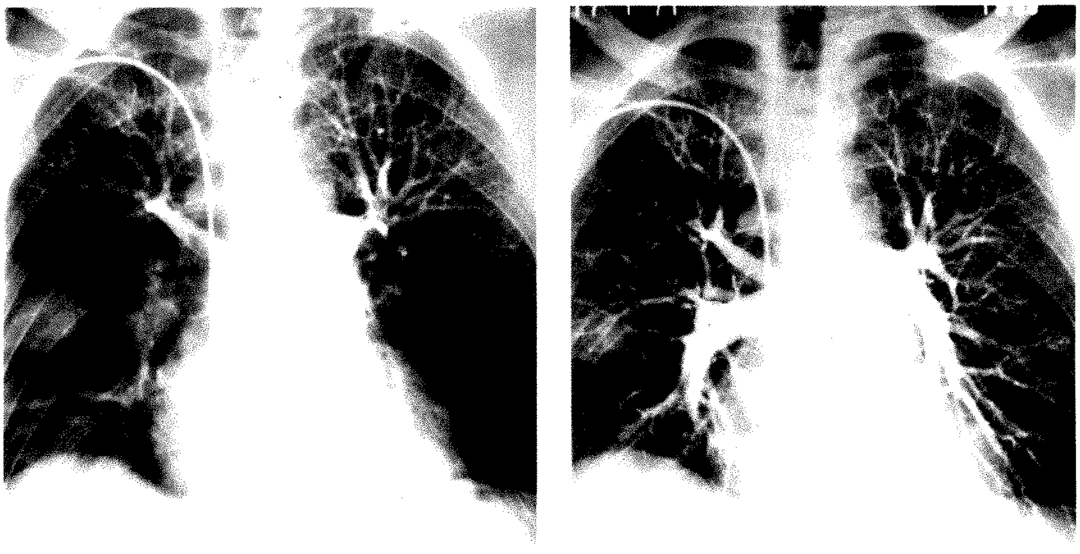

FIG. 2.—Pulmonary arteriograms of a patient with isolated, acute, massive pulmonary embolism on admission (A) and after a 72-hour infusion of streptokinase into the main pulmonary artery (B).

Recently, the effect of either heparin or streptokinas in a series of 23 patients with isolated, acute, massiv pulmonary embolism has been studied. Thes patients are not necessarily comparable with th surgically treated patients and, while no medicall treated patient has died, 2 deteriorated durin treatment (heparin) and 1 of these then had a success ful embolectomy. Equally, by-pass embolectomy i still the treatment of choice in a patient who is s critically ill that the delay in obtaining a respons which is associated with medical treatment is though to be unacceptable. Thus, the good results obtaine with medical treatment have in part depended o the potential which by-pass embolectomy has fo retrieving a deteriorating situation.

The results of the comparison between streptokinas and heparin have been reported elsewhere (Mille Sutton, Kerr, Gibson, and Honey, 1971). In sum mary, patients in the two treatment groups wer shown to be similar in terms of the haemodynami disturbance and the angiographically assessed severit of embolism before treatment was started. Patient were reassessed by repeat catheterization an pulmonary arteriography after a 72-hour treatmen period. Treatment was either with streptokinase* i a dose of 600,000 U. in the first half hour followed b 100,000 U. per hour for 72 hours, or with heparin i a dose sufficient to prolong the whole-blood-clottin time by a factor of 2–3 (40,000–60,000 U. per 24 hours). Steroid cover (hydrocortisone 100 mg. i.v. 6-hourly) was given to the streptokinase-treated patients. In both the groups treatment was by continuous drip into the catheter which was left in the main pulmonary artery and used for the subsequent post-treatment pulmonary arteriogram. Results indicate that streptokinase leads to more rapid lysis of emboli than does heparin both in terms of the haemodynamic and, particularly, of the angiographic response (*Fig.* 2), the differences between the two groups in terms of the post-treatment pulmonary arteriogram being highly significant ($P < 0{\cdot}001$). The only complication of treatment was bleeding from cut-down or operation sites with a fall in haemoglobin, which was more commonly seen in the streptokinase-treated group. In 2 patients treatment with heparin had to be abandoned because of clinical deterioration; this never happened in the streptokinase-treated group.

---

* Kabikinase; Kabi Pharmaceuticals Ltd., Bilton House Uxbridge Road, London, W.5.

That streptokinase results in the accelerated lysis of emboli is a deliberately limited conclusion. Of patients dying from pulmonary embolism, perhaps two-thirds are dead within 2 hours (Gorham, 1961); clearly thrombolytic therapy is unlikely to have much to offer these patients. None the less there remains a significant number who die in the succeeding hours or days; if death in these patients is related to an unrelieved severe haemodynamic disturbance or to further embolism occurring before much of the pulmonary vascular bed has cleared then accelerated lysis of the emboli is a desirable aim. At the present time, however, there is no statistically acceptable evidence that thrombolytic therapy does reduce mortality, though such evidence may be forthcoming. Other aims of treatment include a reduction in the recurrence rate and in the incidence of late sequelae. However, in a multicentre trial of another thrombolytic agent (urokinase) and heparin reported from the United States (Urokinase Pulmonary Embolism Trial, 1970) the recurrence rate and the incidence of incomplete resolution at 1 year were the same in both treatment groups, though this large series contained very few patients with the type of life-threatening massive pulmonary embolism which has been treated in the series reported here.

At the Brompton Hospital the present policy is to use streptokinase as the treatment of choice in isolated, acute, massive pulmonary embolism and to reserve embolectomy (1) for patients with life-threatening pulmonary embolism in whom there is a contra-indication to streptokinase therapy, and (2) for patients whose condition is critical or in whom there is serious deterioration despite medical treatment. Contra-indications to streptokinase therapy are probably also contra-indications to heparin therapy and include recent surgery where bleeding would constitute a risk, known peptic ulceration, and a coagulation defect other than that due to previous anticoagulant therapy. There remains a difficult group of patients in whom embolism is not life threatening but in whom resolution is incomplete or there is a contra-indication to streptokinase therapy. In the first type of patient streptokinase might be employed; embolectomy might be advocated for the second group, although it is not known if the risks of treatment in such patients outweigh the possible gains, bearing in mind that the natural history of pulmonary embolism is probably for eventual resolution to occur in the majority of cases.

REVIEWS AND NOTICES OF BOOKS

Endocrine Therapy in Malignant Disease. Edited by BASIL A. STOLL, F.F.R., London. 9¾ × 7½ in. Pp. 442 + xvi. Illustrated. 1972. London: W. B. Saunders Co. Ltd. £7·50.

THIS work with its fifteen contributors from various parts of the world is in reality a commemorative volume honouring Charles Huggins on the occasion of his seventieth birthday. An interesting short history of the life and work of Charles Huggins is given by Paul Talalay of Johns Hopkins University, and there is a pleasing photograph of Huggins.

Every aspect of the important subject of endocrine therapy in malignant disease has been covered in an interesting and practical way. Charles Huggins himself contributes a fascinating chapter on endocrine-induced regression of cancers.

The volume is divided into five large sections. Section 1 deals with basic considerations. Section 2 is devoted to breast cancer and endocrine therapy. Section 3 is concerned with prostatic cancer. In section 4 other tumours, such as endometrial hyperplasia and carcinoma in situ, are considered. Endocrine therapy in advanced endometrial cancer also comes under review. Section 5 deals with prospective considerations, in which an evaluation of endocrine ablation therapy is discussed in some detail.

This is one of the most important medical works that have been published this year.

As a reference volume it could not be bettered.

Perspectives in Surgery. By CLARE GRAY PETERSON, M.D., Portland, Oregon. 10 × 7 in. Pp. 339 + xvi. Illustrated. 1972. London: Henry Kimpton. £9·45.

THIS is a book that all surgeons will enjoy reading. It is full of useful facts and information and considerations of important conditions with which any surgeon may be faced.

On the inside cover a copy of the Hippocratic Oath is printed in full. Many doctors have never read this oath and it is pleasing to note that the author considers it necessary to bring it into the limelight again.

The book is divided into five parts. Part 1 is concerned with the biological response to injury, which includes systemic and local responses. The electron photomicrographs of a healing wound are excellent. Part 2 deals with balance problems in surgery. The contribution on water–electrolyte balance is quite stimulating. Part 3 is devoted to thermal burns. Part 4 is given up to surgical infections, and Part 5 is concerned with the acute abdomen.

There is a very complete selected list of references and a full index.

A book which makes the reader think and ponder.

Orthopédie et Traumatologie. Conférences d'Enseignement 1970. 8¾ × 6¾ in. Pp. 311. Illustrated. 1971. Paris: Expansion Scientifique Française. No price given.

THIS book mysteriously lacks an introduction but from the title page it may confidently be concluded that it reproduces a postgraduate course given in 1970. If one opens this volume with gloomy forebodings that the contents will only be of interest and worth having t those who attended the course one will be most agreeabl surprised. There are thirteen articles with an averag length of 25 pages, which seems quite fair for the kin of information supplied. The subjects are taken fro the realm of orthopaedics and traumatology and are al of definite current interest. To mention some of them there is an opening chapter of a contemplative nature o the essence of osteo-arthritis that will be upsetting t many an established opinion; there is a section on th operative treatment of ruptures of the rotator cuff of th shoulder, meticulously describing Debeyre's origina approach and, what is more, his late results; there is good synopsis on the ever-bedevilling treatment of hallu valgus, and a fine review of patellar fractures. The boo is well produced, profusely and clearly illustrated, an the text is most lucid. Though there is a good bibliography, this is not a book of reference but one whos study should be very rewarding.

Ano-rectal Malformations in Children. By F DOUGLAS STEPHENS, D.S.O., M.S. (Melb.), F.R.A.C.S. and E. DURHAM SMITH, M.D. (Melb.), F.R.A.C.S. F.A.C.S., Melbourne. 8¾ × 5¾ in. Pp. 411 + xvi. Illustrated. 1972. London: Lloyd-Luke. £11·70.

THIS book which is dedicated to 'Children everywhere deformed anywhere' is a most comprehensive review o anorectal malformations in children.

The first chapter contains an excellent historical revie of these conditions; it is written by Dr. Reginald Webster Pathologist to the Royal Children's Hospital, Melbourne

Following this, some chapters devoted to the anatom and function of the normal rectum and anus are wel illustrated with clear line drawings. Individual deformities in the male and female are well described and illustrated.

A full discussion on the embryology of the rectum an anal canal is included.

The various operative procedures are discussed a length. The results of treatment, complications, an assessment of continence are set out in an interesting an practical manner.

Throughout the book the illustrations are excellent an do enhance the written word.

The references at the end of the book are extensive an cover the international literature on this subject. A first class reference volume which should find a place in ever medical library.

Theatre Nurses Handbook. By ALICE B. CRANFIELD S.R.N., formerly Westminster Hospital, London. 8½ × 5½ in. Pp. 108 + vii, with 22 illustrations. 1972 London: The Butterworth Group. £1·40.

THIS is a useful paperback for the nurse in training an for post-registration nursing staff. It contains a wealt of information on operating-theatre management and i explains the common skin incisions used in surgery.

This short handbook of modest price will be a great ai to nurses in helping them to obtain a better understandin of operating-theatre technique.

Kabikinase®
Streptokinase

Streptokinase
Kabikinase®

Surgical clearance of thromboembolism is often hazardous and troublesome. Clearance with Kabikinase can be a simpler matter, and it often yields superior results: probably because the logic of Kabikinase, highly purified streptokinase, is to potentiate the body's own *natural* ability to dissolve clots.

Kabikinase® (pure streptokinase
for intravascular infusion)
is manufactured by AB Kabi,
Stockholm, Sweden and is
available only from:

KABI

Kabi Pharmaceuticals Ltd,
Bilton House, Uxbridge Road,
Ealing, London W5 2TH
Telephone: 01-567 4717 or
01-579 1871

A handbook of information about thrombolytic therapy with Kabikinase will be sent on request.

ABDOMINAL AND VAGINAL HYSTERECTOMY

New Techniques Based on Time and Motion Studies

S. Joel Cohen, MB, BCH, FRCS, FRCOG, FICS, Founder FCOG (SA), DObstRCOG, LM.

Mr. Joel Cohen is recognised throughout the world as a master of gynaecological surgery. In this book he describes his techniques of hysterectomy in sufficient detail for other surgeons to try to adopt his methods, even if, to quote Sir Norman Jeffcoate, "they have not had the unique experience of seeing the master at work". The illustrations, numerous and detailed, enhance the succinct clarity of the text. To quote Sir Norman again, "this beautiful work must inevitably come to occupy an important place in the literature of our speciality."

168 pages **157 illustrations** **£3·50 net**

HEAD AND NECK SURGERY

P. M. Stell, FRCS, and A. G. Maran, MD, FRCS.

This title covers comprehensively head and neck surgery from the preoperative considerations through to operative technique, postoperative care and the general complications of head and neck surgery. Tumours (such as tumours of the larynx and cervical trachea, the nose and sinuses and the oral cavity) are also included.

464 pages **278 illustrations** **£7·50 net**

LIVINGSTONE**

MANUAL OF SURGICAL THERAPEUTICS

Edited by R. E. CONDON and L. M. NYHUS

1970 *390 pages* *48 illustrations*

Spiral bound **£3·25**

The authors provide comprehensive information on the diagnosis and treatment of shock, trauma, and cardiac disorders. Preoperative and postoperative care are covered in detail. Surgical infections, bacteriology, and complications are discussed with complete sections on drug usage, side effects, and administration.

RENAL TRANSPLANTATION

JEAN HAMBURGER, JEAN CROSNIER,
JEAN DORMONT, and JEAN-FRANÇOIS BACH

1972 *346 pages* *49 illustrations* **£7·00**

The team of surgeons responsible for the first kidney transplant in 1952 have written this new book to share their experience of 20 years' work in the field with surgeons, immunologists and nephrologists. The authors contend that transplantation is not practicable without a full appreciation of all the problems, ranging from the immunology laboratory to the operating theatre. In considering both theory and practice, they have made a major contribution to one of the most exciting scientific adventures in human experience.

THE ALCOHOLIC PATIENT IN SURGERY

ALBERT B. LOWENFELS

1972 *280 pages* *81 illustrations* **£6·00**

The observations contained in this book result from 20 years' experience at hospitals in which a unique opportunity existed for the study of the alcoholic patient.

All surgeons who treat alcoholic patients recognize that they pose a continuing challenge in both a diagnostic and therapeutic sense.

John Wright SELECTED TITLES

Emergency Surgery

Ninth edition. Edited by T. J. McNAIR, M.D., F.R.C.S. (EDIN.), F.R.C.S. (ENG.), Consultant Surgeon, Royal Infirmary of Edinburgh.

Extensively revised and with about 200 new illustrations, the theme of this book still remains: when to operate, when not to operate, and how to operate under emergency conditions.

998 *pages* 1155 *illustrations* **£12·50**

Fundamental Physics of Radiology

Second edition. W. J. MEREDITH, O.B.E., D.SC., F.INST.P., Director of Physics, Christie Hospital and Holt Radium Institute; and J. B. MASSIE, B.SC., F.INST.P., Physicist, Christie Hospital and Holt Radium Institute.

In the second edition a new chapter on the treatment prescription and an appendix on modulation transfer functions have been added.

674 *pages* 460 *illustrations* **£6·25**

The Arterial Anatomy of the Kidney

F. T. GRAVES, M.S., F.R.C.S., Urological and Senior Surgeon, Staffordshire General Infirmary, Stafford.

This book is a complete work of reference on the vascular and arterial systems of the kidney, based on investigations covering many years. With the ultimate aim of improving renal surgery, a complete chapter on surgical technique has been included.

116 *pages* 75 *illustrations* **£3·25**

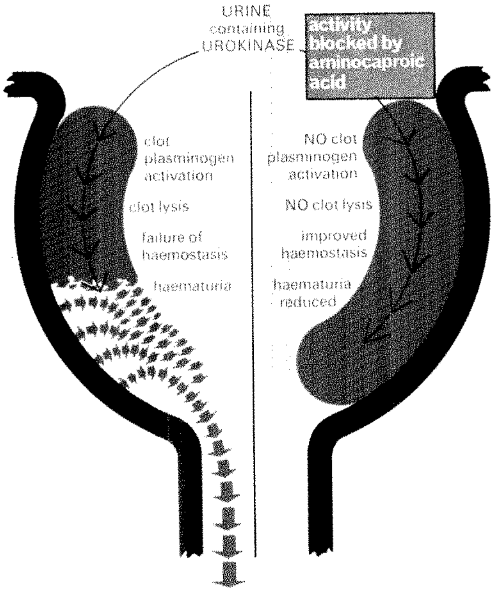
The mechanism of post-prostatectomy bleeding and EPSIKAPRON® control



URINE containing UROKINASE
activity blocked by aminocaproic acid
clot plasminogen activation
clot lysis
failure of haemostasis
haematuria
NO clot plasminogen activation
NO clot lysis
improved haemostasis
haematuria reduced

Epsikapron (aminocaproic acid) is rapidly excreted in the urine in high concentration; there it inhibits urokinase, the fibrinolytic enzyme in urine. With the haemorrhage-sustaining property of urine blocked, the haemostatic coagulum becomes adequate, and blood loss is diminished substantially.

Epsikapron makes your prostatectomy patient's post-operative course smoother by diminishing:

the need for post-operative blood transfusion

clot retention

catheterization

the risk of infection

the period of hospitalization

Presentation

Epsikapron Solution for Injection 0.4 g/ml Box of 6 ampoules of 10 ml, each containing 4.0g aminocaproic acid (0022/5003) Epsikapron Effervescent Powder 50% Box of 30 sachets, each containing 3.0g aminocaproic acid (0022/5004) Epsikapron Syrup 0.3g/ml Bottle of 250ml (0022/5005)

EPSIKAPRON®

OP-SITE BARRIER

TRADEMARK

The most effective adhesive drape

Unlike other sterile adhesive drapes, Op-site can breathe.

Which puts it at something of a premium. Because it allows a continual exchange of gases: oxygen to the skin, water vapour away from it.

There's no maceration of tissue and no perspiration build up to loosen the adhesive. Just total conformability and strict adhesion throughout.

Because of this, Op-site may be sutured through and left to protect the skin till the stitches are removed.

Post-op protection makes sense. Use Op-site.

Hospital Medicine at its best

PRINTED IN GREAT BRITAIN BY JOHN WRIGHT AND SONS LTD., AT THE STONEBRIDGE PRESS, BRISTOL BS4 5NU

THE BRITISH JOURNAL OF SURGERY

ISSUED MONTHLY

NOVEMBER, 1972

BRISTOL: JOHN WRIGHT & SONS LTD.
WHOLESALE DISTRIBUTORS: WM. DAWSON & SONS LTD., CANNON HOUSE, FOLKESTONE
SOLE AGENTS: CANADA: THE MACMILLAN CO. OF CANADA LTD., TORONTO
UNITED STATES OF AMERICA: THE WILLIAMS & WILKINS CO., BALTIMORE
Second class postage paid at Baltimore, Maryland, and at additional mailing offices

Why Dexon*?

1. Easy to handle–similar to silk or linen thread
2. Packed dry–convenient to use
3. High tensile strength–excellent wound support
4. Smaller gauges needed for comparable strength compared with gut
5. Braided construction–secure knots–more security
6. Predictable absorption even in contaminated areas
7. Minimal tissue reaction and inflammatory response
8. Improved patient comfort
9. Permits undisturbed wound healing
10. Less painful wounds
11. Shorter hospitalization
12. Improved cosmetic results especially with subcuticular stitches
13. Is there when it is needed, but has gone when it is not
14. Multi-uses means greater economy
15. May be removed as usual when used for skin sutures but may be left to absorb if preferred–e.g. paediatric surgery, under orthopaedic plaster casts, episiotomy repairs, circumcisions, etc.
16. Simplified stock holding, laying up for operations, nurse training
17. It is supplied on the best suture needles made

Why not?

1. The braided construction may mean an initial difficulty in tying knots
2. A slight increase in tissue-drag may be experienced. Can be improved by wetting
3. Absorption of blood and other body fluids may make Dexon more difficult to see
4. Suture for suture it appears to be more expensive than other materials –cost in use is probably less
5. It is different and you may need to especially ask for it

Dexon* the suture that supersedes catgut

EDITORIAL NOTICES

EDITORIAL COMMUNICATIONS should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol, BS8 1EX.*

Original Articles are invited, and should be sent, whenever possible, to a member of the Editorial Committee: they are accepted with the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

REPRINTS can be supplied at a reduced price if authors indicate their requirements at the time that proofs are returned. The following scale will be helpful as a guide to the cost; 50 copies are suggested as a minimum number.

NO. OF PAGES	NUMBER REQUIRED							
	50	100	150	200	250	300	400	500
2	£2·83	£3·70	£4·27	£5·07	£5·69	£6·32	£7·74	£8·99
4	3·58	5·19	6·09	7·12	8·07	9·09	10·97	12·97
6/8	5·94	7·62	9·27	10·84	12·59	14·09	17·47	20·72
10/12	9·32	12·72	15·09	17·72	20·34	22·97	28·40	33·05
14/16	10·37	14·34	17·47	20·59	23·72	27·03	33·18	39·55

COVERS	1·94	2·75	3·57	4·38	5·19	6·00	7·63	9·25

An extra 16p per 300 pages will be charged for reprints sent to outside the United Kingdom.

An additional charge will be made for reprints containing coloured illustrations, depending upon the amount of extra work involved.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol, BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 58. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

BACK NUMBERS.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

ADVERTISEMENTS.—All communications should be addressed to *H. S. Janes & Partners Ltd., St. Martin's House,* 159 *Clapham High Street, London, S.W.4.*

INSTRUCTIONS TO AUTHORS

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

TABLES AND ILLUSTRATIONS.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too, should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

REFERENCES.—The arrangement is based on the Harvard System.

In this system the name of the author and the date of the publications are given in the text; the list of authors quoted is put at the end of the article in alphabetical order. Each reference in the list should give, in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volume (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has written more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, the place of publication should be stated and the publisher's name. The names of collaborating authors should be given in full on the first occasion, but in later citations the words "and others" should follow the first name. Abbreviations for journals should be those adopted in the "WORLD LIST OF SCIENTIFIC PERIODICALS" (1963).

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names.

ICI introduces the

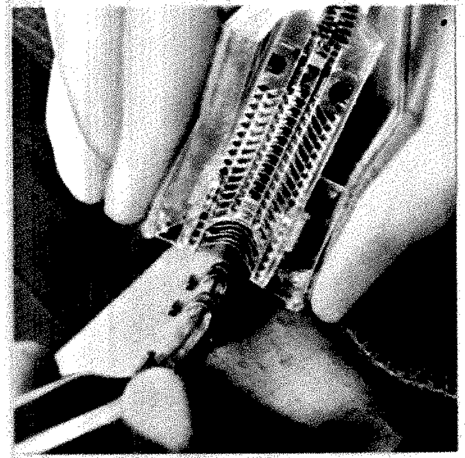
AVLOX 18

Trade Mark

SYSTEM

The AVLOX 18 System from ICI provides a new and simple method of wound closure.

Simply hold the wound edges together with forceps and apply clips along the length of the wound.



Obviously this technique offers advantages. It is fast, easy to use and convenient. It reduces the risk of permanent marks because the clips hold and do not generally penetrate the skin.

The AVLOX REMOVER (also illustrated) has been specially designed to minimise discomfort during clip removal.

Both the AVLOX 18 and the AVLOX REMOVER are supplied sterile and ready for use.

FOGARTY CATHETERS FOR ACUTE VASCULAR OCCLUSION

FOR: Venous Thrombectomy

Occlusion/Emergency Tamponade

Arterial Embolectomy

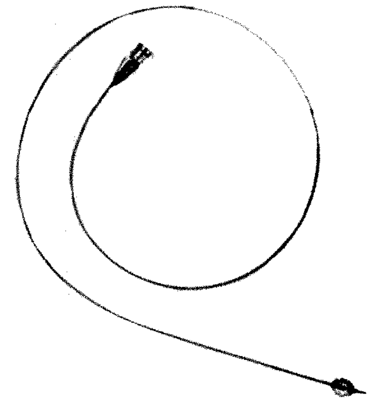
Dilation/Creation of Atrial Septal Defects in Infants

Double Lumen Balloon Catheter/Creation of Atrial Septal Defects in Infants

Biliary Balloon Probe/Exploration and Removal of Debris and Stones

Irrigation

Rugged Universal Hub Fits All Luer-Lok Type Syringes



BALLOON CATHETER CONCEPT

Each catheter has a specially constructed balloon at the distal tip (except Irrigation Catheter). In thrombectomy and embolectomy, when the catheter is introduced into a vein or artery, the instrument follows the path of least resistance and the tip threads itself past the thrombus or plaque. The balloon is then inflated with sterile fluid and the catheter withdrawn, bringing the clot with it. As an emergency tamponade, for dilation, or as a biliary probe, the balloon is similarly inflated.

GENERAL DESIGN FEATURES

1. Tips on the various types are specially designed for the particular procedure; all are soft and atraumatic.
2. Controlled symmetrical balloon geometry.
3. Secure balloon attachment by epoxied suture.
4. Length marked catheter bodies.

ALL FOGARTY CATHETERS ARE SUPPLIED STERILE

For rapid, safer post operative wound healing
Redivac closed suction apparatus
TO PREPARE
KEEP UPRIGHT
Zimmer

First intention wound healing after operation is prolonged by the accumulation of tissue fluids and blood at the site. This accumulation often encourages infection.

The problems associated with these traditional procedures are solved by Redivac Closed Suction Apparatus, which removes blood and tissue fluids and avoids the formation of haematoma.

The Redivac evacuator bottle supplies a negative pressure of 600 mm Hg. The drainage tube is laid in the wound and is passed through intact skin, some distance from the incision. It is then connected to the evacuator bottle and suction commenced.

The Redivac Closed Suction System is simple, inexpensive and comfortable for the patient. It is applicable in all deep surgical procedures. The Redivac Closed Suction System facilitates nursing and results in shorter hospitalisation of patients.

SPECTROLITE

THE SUPERB RANGE OF LIGHTWEIGHT, THORACIC RETRACTORS!

The Thackray Spectrolite range is a new concept in Thoracic Retractors and Rib Spreaders. The various models are precision made in lightweight alloy combining optimum strength with ease of handling. The blades and arms are finished in non-glare black, the gear track in non-glare satinised alloy for minimum optical distraction and strain in the theatre.

Send for illustrated literature of the full range.

ORIGINAL PAPERS

IVALON (POLYVINYL ALCOHOL) SPONGE IN THE REPAIR OF COMPLETE RECTAL PROLAPSE

By SIR CLIFFORD NAUNTON MORGAN,
HONORARY CONSULTING SURGEON, ST. BARTHOLOMEW'S AND ST. MARK'S HOSPITALS, LONDON

NIGEL H. PORTER,
CONSULTANT SURGEON, BRIGHTON AND LEWES GROUP OF HOSPITALS

AND DAVID J. KLUGMAN
SENIOR REGISTRAR IN ORTHOPAEDICS, KING'S HOSPITAL, LONDON

SUMMARY

One hundred and fifty cases of complete rectal prolapse have been operated on using an Ivalon-sponge implant, the first case being over 13 years ago. Seventy per cent of the patients were over the age of 60 years. The operation has a low mortality- and morbidity-rate. Repair using Ivalon sponge was 96 per cent successful in the cure of complete prolapse and the method appears to stand the test of time well.

In 1959 Wells first described the use of polyvinyl alcohol sponge in the repair of rectal prolapse. A follow-up study (Morgan and Wells, 1962) suggested that this technique provided a very effective method of controlling rectal prolapse and that it also went some way towards helping in the management of the notoriously difficult functional problems that beset these patients, in that 50 per cent of them became continent postoperatively and, as a result of this, were able subsequently to manage their difficult bowel habits more easily.

We have delayed publication of our figures for two reasons: first, in order to gain a significant number of patients for a worth-while statistical evaluation, and, secondly, to see how this operation stands the test of time. In the management of complete rectal prolapse these two considerations are important.

The vast amount of literature published on this subject contains a number of extravagant claims based on small series of cases which have been insufficiently followed up. We have taken considerable trouble to avoid this error in the present series.

MATERIALS

This series of 150 patients was operated on by two of us (C. N. M. and N. H. P.) between January, 1959, and May, 1972 (*Table I*). There were 127 females and 23 males. The age-range was 24–86 years with a mean of 65 years. Seventy per cent of the patients were over 60 years of age. Out of the 150 patients, 4 patients (2·6 per cent) died in the early postoperative period. There were 11 late deaths (7·3 per cent) in the series—these patients died from causes unconnected with the original operation or complaint of rectal prolapse. In none of these patients was there any history of recurrence up to the time of death. Unfortunately, 42 patients (28 per cent) have been lost to follow-up because they had originally come from distant parts of the United Kingdom or from abroad. In none of these latter patients was there any history of recurrent prolapse up to the time of their disappearance from follow-up. Thus, there is a total of 93 cases (62 per cent of the number operated on) available for study.

Table I.—THE CASE MATERIAL IN THE PRESENT SERIES

	No. of Cases	*Percentage*
Early postoperative deaths	4	2·6
Late deaths from other causes	11	7·3
Cases lost to follow-up	42	28·0
Cases studied fully	93	62·0
Total	150	

METHODS

Preoperative Investigation.—A number of patients were investigated both pre- and postoperatively by means of cine-radiography during defaecation (Fry, Griffiths, and Smart, 1966). Postoperative studies showed good fixation of the rectum in the sacral hollow and improvement in the position of the levator muscular shelf on which the distal portion of the rectum lies.

Pre- and postoperative electromyographic studies of the pelvic floor were carried out in some patients. In all the patients there was a gross disturbance of the normal postural pelvic floor reflexes preoperatively, and in only 2 of the patients who were followed up postoperatively (both were young) was there any significant recovery in the pelvic muscle function, which indicates that whatever the cause of the prolapse may be (and we think it is due to abnormal habits of defaecation to a large extent) these aetiological factors produce muscle failure in the pelvic floor before prolapse which is not cured by fixing the rectum in the sacral hollow.

These observations are in keeping with those of Parks, Porter, and Hardcastle (1966) on the 'descending perineum' syndrome and they also go some way towards explaining the fact that correction of the rectal prolapse alone does not entirely solve the functional problems of continence and abnormal bowel habit.

Operation.—The operative technique used in the present series is described by Morgan and Porter (1969) and by Morgan (1973).

RESULTS

Mortality.—There were 4 early postoperative deaths (2·6 per cent). Three of these were due to unassociated disease—2 women, aged 59 and 73 years respectively, from coronary occlusion on the fifteenth and tenth postoperative days and 1 woman of 75 years following a pulmonary embolus on the sixth postoperative day. The fourth death was attributable to the operation. This occurred in a woman of 86 years and was due to intestinal obstruction on the fifth postoperative day. At laparotomy on the sixth postoperative day she was found to have a small-bowel volvulus which was the result of an antemesenteric adhesion to the reconstituted pelvic floor. Small-bowel resection and anastomosis were performed but the patient died on the eighth postoperative day. There have been no further early postoperative deaths in this series since 1964.

Morbidity.—

Sepsis.—Four patients (2·6 per cent) have developed pelvic sepsis directly attributable to the operation. These 4 patients bear careful scrutiny as the implantation of foreign plastic materials must always constitute a hazard in this respect.

Case 1.—Female, aged 56 years. This patient developed a postoperative low-grade pyrexia and leucocytosis for which no cause could be found at first. Pelvic examination, although initially negative, revealed after 5 months a boggy swelling around the rectum, rather than the usual perirectal induration, which was palpable high in the pelvis. There was no suitable response to antibiotics and therefore the decision was taken to remove the Ivalon sponge. This was effected through an abdominal incision. Thereafter the patient made an uneventful recovery and has had no further prolapse.

Case 2.—Female, aged 83 years. This patient made uneventful progress for the first week after operation. On the eighth postoperative day she developed a vaginal discharge and pyrexia. Examination revealed a diathermy slough in the posterior vaginal fornix through which infection had entered the pelvic cavity. There was no satisfactory response to antibiotics. On the sixteenth postoperative day under general anaesthesia the orifice in the posterior vaginal fornix was enlarged and the Ivalon sponge was removed without difficulty. Thereafter the sinus in the vagina healed. The patient completely recovered and has had no further prolapse.

Case 3.—Female, aged 73 years. This patient developed persistent pyrexia from the first postoperative day. This was associated with leucocytosis and examination revealed a boggy swelling surrounding the rectum. On the eighth postoperative day she had purulent diarrhoea, and sigmoidoscopy showed a fistula into the rectum at 8 cm. through which pus was draining. Following drainage per rectum the patient's constitutional symptoms remitted, but she continued to have uncontrollable diarrhoea. For 6 weeks unsuccessful attempts were made to manage this conservatively. Seven weeks after the original operation under general anaesthesia the sinus in the posterior wall of the rectum was enlarged and the Ivalon sponge was identified, grasped with sponge-holding forceps, and removed. Postoperatively the patient made a complete recovery: the rectum healed, the pelvic infection subsided, and the patient lost her diarrhoea and gained full faecal control. She has since had no further prolapse.

Case 4.—Female, aged 76 years. This patient underwent repair of her rectal prolapse with an Ivalon-sponge implant in 1964 with an uneventful recovery and complete control of her rectal prolapse and bowel function subsequently. Eighteen months later at routine follow-up she complained of a dull aching sacral pain. Digital rectal examination revealed a boggy, tender swelling posterior to the rectum. Sigmoidoscopy confirmed the presence of a posterior bulge into the rectum above the anorectal ring. The patient had no constitutional symptoms or pyrexia. The total white-blood count was 12,000 c.mm. with a pronounced left shift and a polymorph count of 78 per cent. Antibiotics were exhibited without effect and the patient's sacral pain increased. Finally, under general anaesthesia the posterior bulge into the rectum was explored by means of sinus forceps passed via the rectal lumen. A quantity of pus was drained and digital exploration revealed a loculated cavity behind and on either side of the rectum in which fragments of Ivalon sponge could be felt; these were removed with sponge-holding forceps and the cavity was irrigated. The abscess cavity thereafter rapidly closed down and the opening into the rectum healed. The patient lost her pain and there has been no recurrence of prolapse or loss of continence.

Cure of Prolapse.—Out of 93 completely documented cases, 90 (96·8 per cent) have been cured of complete rectal prolapse (*Table II*). There have been 3 cases (3·2 per cent) of recurrent complete prolapse. All the complete recurrences occurred within 3 years of operation. The earliest of these was in a male of 60 years whose prolapse recurred at 7 months. He had a history of intractable diarrhoea following amoebic dysentery many years previously. The repair of the rectal prolapse had made no difference to his bowel habit. The other 2 complete recurrences were in women, one aged 60 years and the other aged 82 years. Both of these patients had had a previous rectosigmoidectomy. Prior to operation they had been totally incontinent and they had only been able to manage their bowel habits socially by making sure that they were grossly constipated. Both patients had had a completely patulous anus preoperatively. Pre- and postoperative electromyographic studies revealed an almost total loss of pelvic postural reflexes and continence reflexes. In addition, in each case balloon studies showed a rectal capacity of less than 50 ml. and neither patient was able to retain the balloon in the rectum. There was no postoperative improvement in continence or bowel habit.

Table II.—RESULTS OF REPAIR OF COMPLETE RECTAL PROLAPSE USING IVALON SPONGE

	No. of Cases	*Percentage*
Total No. of cases	93	
Cured of complete prolapse	90	96·8
Recurrent complete prolapse	3	3·2
Persistent mucosal prolapse	8	8·6
Further operation for mucosal prolapse	4	4·3
Further operation for incontinence	7	7·5

It is worthy of note that there have been no recurrences after the lapse of 3 years postoperatively. *Table III* provides a breakdown of the duration of follow-up in annual periods. There are 104 patients who were operated on over 3 years ago: 56 of these patients come into the total follow-up group and none of them has developed a complete recurrence, although 7 have developed mucosal recurrence. These figures indicate that complete recurrence is uncommon and, if it occurs, it does so relatively early.

Table III.—DURATION OF FOLLOW-UP OF 128 CASES WHO HAD UNDERGONE OPERATION FOR COMPLETE RECTAL PROLAPSE

YEAR	NO. OF CASES	NO RECURRENCE	MUCOSAL RECURRENCE	COMPLETE RECURRENCE	LOST TO FOLLOW-UP BUT NO RECURRENCE	DEAD FROM OTHER CAUSES (NO RECURRENCE AT THE TIME)
0–1	15	8	0	1	4	2
1–2	16	6	2	0	6	2
2–3	15	4	2	2	4	3
3–4	14	7	1	0	5	1
4–5	9	7	0	0	2	0
5–6	11	3	1	0	6	1
6–7	14	9	2	0	1	2
7–8	7	5	1	0	1	0
8–9	9	9	0	0	0	0
9–10	5	4	1	0	0	0
10–11	4	3	1	0	0	0
11–12	5	5	0	0	0	0
12–13	2	2	0	0	0	0
13–14	2	2	0	0	0	0
Total	128	74 (57·8 percent)	11 (8·6 per cent)	3 (2·3 per cent)	29 (22·6 per cent)	11 (8·6 per cent)

Eight patients (8·6 per cent) in this series prolapsed mucosa only through the anal canal at some time postoperatively. Half of these patients failed to respond to submucous injections of 5 per cent phenol in almond oil and because their symptoms troubled them they required a further operative procedure, viz., ligature and excision. This simple procedure was sufficient to relieve them of further mucosal prolapse.

Bowel Habit.—Accurate knowledge of bowel habit prior to the onset of prolapse is available for 103 cases. *Table IV* indicates that only 20 patients (19·4 per cent) had had a regular bowel habit before they developed prolapse. Eighty-three patients (80 per cent) had had an abnormal bowel habit; 67 (65 per cent) having been constipated and 16 (15·5 per cent) having had diarrhoea or loose motions more than three times a day.

Constipation has been defined for the purpose of this study as a bowel habit involving routine straining at defaecation to pass hard stools. This may also be associated with several attempts to defaecate daily in order to satisfy a feeling of incomplete defaecation whether the act is productive of a stool or not. Also included in this group are those patients who failed to open their bowels more than three times a week. These criteria are similar to those of Connell, Hilton, Irvine, Lennard-Jones, and Misiewicz (1965).

Table IV.—BOWEL HABIT IN 103 CASES OF COMPLETE RECTAL PROLAPSE

BOWEL HABIT	BEFORE ONSET OF PROLAPSE		AFTER OPERATION	
	No. of Cases	Percentage	No. of Cases	Percentage
Regular	20	19·4	60	58·2
Constipation	67	65·1	28	27·2
Diarrhoea	16	15·5	15	14·6
Total	103	100·0	103	100·0

The postoperative figures show a striking improvement in that 60 patients (58·2 per cent) have been converted to a regular bowel habit, 28 (27·2 per cent) have remained constipated, and 15 (14·6 per cent) have frequent loose stools. This latter figure is not significantly changed, nor would one expect it to be.

It must be emphasized that the conversion from constipation to a regular bowel habit is in the majority of cases achieved by the use of aperients and this is only possible because control of rectal prolapse allows a more rational use of aperients. Careful and prolonged follow-up involving, in many cases, much trial and error in the choice of the right aperient is essential if any improvement in bowel habit is to be achieved and maintained. Furthermore, patients will not tolerate the regular ingestion of aperients unless their continence has been improved. Control of prolapse and improvement in continence also allow the use of suppositories and the avoidance of straining in those patients who do not respond satisfactorily to aperients.

Continence.—For the purposes of this study we have defined incontinence as the uncontrolled leakage of solid or loose stool. The degree of incontinence within these criteria varies from gross to slight. The results are not, however, graded according to severity as attempting to do so makes statistical evaluation useless.

Prior to operation 83 patients (80·6 per cent) were incontinent (*Table V*). Postoperatively 40 patients (38·8 per cent) were incontinent.

Continence is not always established immediately after the operation. Careful supervision of the diet and an aperient régime are essential to achieve the best results and must be aided by sphincter exercises, and sometimes pelvic faradism, to re-educate the pelvic muscles. Continence improves in many patients over the first 6–12 months. During this time a number of patients transfer from the incontinent to the continent group. This is an important point in management, since this is the most distressing symptom, both pre- and postoperatively. It is worth resisting demands for further operative treatment for incontinence until a year has passed, if the patient can be persuaded to wait that long.

Table V.—CONTINENCE IN 103 CASES OF COMPLETE RECTAL PROLAPSE BEFORE AND AFTER OPERATION

	BEFORE OPERATION		AFTER OPERATION	
	No. of Cases	Percentage	No. of Cases	Percentage
Incontinent	83	80·6	40	38·8
Continent	20	19·4	63	61·2
Total	103	100·0	103	100·0

Further Operations for Incontinence.—Seven patients (7·5 per cent) of the 93 cases who were fully followed up (or 6·8 per cent of those patients who were followed up in respect of continence alone) had further operative treatment for incontinence (*Table II*). Two patients had a Thiersch wire inserted and 1 of these was subsequently continent. The other patient developed sepsis around the wire. The infecting organism was sensitive to chloramphenicol only and the patient was given this antibiotic. She then developed pancytopenia as a complication and died.

Four patients had a post-anal nylon-floss repair (Parks, 1967); 3 of these were subsequently fully continent. The fourth patient was 1 of the 2 women who had had a previous rectosigmoidectomy and who subsequently suffered a complete recurrence after the second year. As a result of the post-anal repair both her recurrent prolapse and incontinence were diminished but not cured. The seventh patient was persistently incontinent after an Ivalon-sponge repair and subsequently had a colostomy. Although thus relieved of faecal incontinence, she still suffered intermittent and uncontrolled excessive discharge of rectal mucus which was socially embarrassing. Subsequently, the rectum was excised by Hartmann's operation with relief of this distressing symptom.

In the remaining 33 patients out of the original 40 who were incontinent following the insertion of an Ivalon sponge, incontinence varied from a slight leak to gross lack of control. They were all relieved of their prolapse following operation and in this respect felt much improved. The majority managed their incontinence. This was no trouble to those with a slight occasional leak, while others opted for a pad since they wished to avoid further operation, although there is little doubt that some of them could have been improved by a further perineal procedure.

DISCUSSION

Any operation designed to cure complete rectal prolapse must be safe and effective. The majority of patients are female and elderly since the incidence of rectal prolapse rises steeply towards the seventh decade (Porter, 1962). It has been our practice to include all patients whatever their age who have a complete rectal prolapse, whether it is primary or has recurred after some other procedure, provided that the patient is fit enough for a major lower abdomi surgical procedure. In any patient with cardi respiratory disease or in whom there was any dou about fitness we have obtained the prelimina opinion of a consultant physician and anaestheti Those patients excluded on medical or anaesthe grounds have been treated by a Thiersch operati A few of those so treated in whom this operation h failed have subsequently been submitted to an Ivalo sponge operation with success. This procedure c be performed in such cases provided that on revi both the patient and the anaesthetist are prepared accept the increased risk.

In spite of these wide criteria of selection the ea postoperative death-rate was only 2·6 per cent. T deaths of the 2 patients from coronary occlusi were unavoidable. The third patient, who died o pulmonary embolus on the sixth postoperative d was operated on in 1964. She was grossly obe With modern methods of prevention, such as su cutaneous heparin (Kakkar, 1971) or galvanic ca muscle stimulation (Powley, 1969), it is possible t pulmonary embolism, a complicating factor in ma pelvic surgery, may be partly eliminated. The fou death in a woman of 86 who developed a small-g volvulus as the result of a pelvic adhesion emphasi the need to reconstitute the pelvic peritoneal fl with care and making quite sure that the Ival sponge is completely extraperitonealized. The f that there have been no further early postoperati deaths in this series since 1964 does not indicate a alteration in our criteria for case selection.

The 4 patients who developed pelvic sepsis ha been carefully studied as there is always a considera risk of infection occurring after the implantation foreign plastic materials. Three precautions are tak to prevent sepsis. First, the patient has a 5-d preoperative course of phthalylsulphathiazole, 2·5 6-hourly, and has routine preoperative bov cleansing including a careful régime of colonic was outs. Secondly, at the time of implantation of t sponge the pelvic cavity is dusted with an antibio powder. Originally this was a mixture of penicil and sulphonamide. Latterly we have used polybact or 1 g. of chloramphenicol powder (Kemicetin Thirdly, postoperatively the patient has a 7-d course of ampicillin, 500 mg. intravenously 8-hour It is also our rule that if any injury occurs to t bowel during dissection, an Ivalon-sponge impla operation should be abandoned. Fortunately this h not happened in our series.

Nevertheless, in spite of these precautions 4 cas of sepsis have occurred. In 1 of them it was clea avoidable. In this patient (*Case* 2), a female aged troublesome bleeding in the region of the posteri vaginal fornix occurred during the mobilization the rectum. The bleeding was controlled diathermy which was clearly over-enthusiastic a led to a slough in the posterior vaginal wall. We ha since exercised great restraint in using diathermy this situation and have controlled any haemorrha with hot packs, pressure, or direct ligation.

In 2 patients (*Cases* 1 and 3) in whom sep occurred within 10 days of the operation infecti must have been due to the introduction of organis at the time of operation, either by the surgeon or failure to sterilize the Ivalon sponge adequately.

the latter respect the makers give detailed advice on the method of sterilization which we have followed carefully as the standard procedure in all cases. We therefore feel that this cause is highly unlikely.

The fourth case (*Case* 4) of sepsis is inexplicable. It occurred 18 months after the operation for no obvious cause. We have no rational explanation to offer.

From our experience it is clear that should sepsis occur, an expectant policy is not justified. As soon as the diagnosis is certain removal of the sponge is a matter of urgency. If an abscess points into the vagina or rectum removal through the wall of either viscus is a simple matter, and in the 3 patients in whom this has been performed resolution has been complete and there has been no recurrence of the prolapse. In 1 other patient the diagnosis was less certain and the abdomen was re-explored from above, the Ivalon sponge was removed, and the abscess was drained. Again, full and satisfactory resolution occurred and this patient has had no further prolapse. It is probable that the advent of sepsis, though highly undesirable, produces the same effect as the Ivalon sponge in that it anchors the rectum to the pelvic parietes by fibrosis.

Polyvinyl alcohol sponge has been shown to be carcinogenic in rats (Oppenheimer, Oppenheimer, and Stout, 1948). A careful study by Walter and Chiaramonte (1965) confirmed the incidence of sarcoma in rats but only when the implant was thick and bulky (Dukes and Mitchley, 1962). Furthermore, in the rat there is a species susceptibility to the induction of neoplasms by a variety of implants, even stainless steel. There is no evidence that polyvinyl alcohol sponge is carcinogenic in man. Clinical use over the past 20 years bears out this conclusion.

We feel that a mortality of 2·6 per cent and a morbidity of 2·6 per cent constitute a reasonable safety level for major pelvic surgery in patients of an advanced age-group and also indicate that the operation is safe.

The second criterion of effectiveness is also satisfied in that in 93 cases who were studied fully there was a complete cure rate of 96·8 per cent. Furthermore, the operation stands the test of time. All the recurrent complete prolapses occurred within 3 years. Two of the patients in whom prolapse recurred had had a previous rectosigmoidectomy and such patients always present a notoriously difficult salvage problem (Porter, 1962). The third case of recurrence, in a male with post-dysenteric diarrhoea, occurred earlier and has not been significantly improved by a subsequent left hemicolectomy and anterior resection.

Mucosal prolapse appearing after operation is difficult to evaluate in that rectal fixation by Ivalon sponge does nothing for the associated inevitable mucosal redundancy. In those patients in whom it did appear (8·6 per cent) it was unnoticed subjectively in half of them, the remainder being discovered only on examination at routine follow-up. All of these patients considered it a trivial complaint compared with their previous complete prolapse. Nevertheless some anxiety is always felt by the clinician in case the advent of mucosal prolapse presages a complete recurrence, and therefore it was usually controlled by submucosal injections of 5 per cent phenol in almond oil whenever it was seen. In 4 patients in whom this simple measure was unsatisfactory, the prolapsing mucosa was excised with a satisfactory result.

In this respect we would emphasize the importance of prolonged follow-up of these patients. There is no doubt that mucosal prolapse causes leaking of faecal-stained mucus with itching and discomfort. Control of mucosal prolapse will improve the patients' incontinence and therefore their attitude towards the use of aperients or suppositories in the management of their bowel habit. In our experience this aspect of follow-up, in particular, repays a good deal of trouble and care.

The elimination of complete prolapse does in itself little for the abnormalities of bowel function which lead to constipation or diarrhoea. However, a major factor in persistent inhibition of the voluntary pelvic muscles and stretching and incompetence of the involuntary internal sphincter is removed. This allows the residual function in both these groups of muscles to work to a better advantage and thus to exercise greater control over the contents of the rectum and to restore some sensory appreciation of impending defaecation to the patient. The majority of patients can, therefore, regulate their bowels better with a more satisfactory knowledge of impending defaecation and have time to reach a lavatory. The patients who have become continent after operation have a variable degree of urgency of defaecation and some can only restrain the act with difficulty, but all of those who have been classified in our results as continent can restrain themselves for a sufficient length of time to reach a lavatory, otherwise they have not been classed as continent.

We have made no attempt to classify continence quantitatively, as we feel that such an attempt would be more confusing than useful. Nevertheless, the degree of incontinence varies greatly, from a slight leak, when the patient has liquid stools, to gross soiling with solid stools. It is worth waiting 6 months to a year, preferably the longer period, for continence to improve if it is not satisfactory immediately postoperatively.

Improvement appears to be due to three factors. First, the patients learn to adjust their aperient régime better and also find a suitable aperient. In this respect, the aperient found to be most useful is a bulk-forming one such as Normacol. The second factor is that the operation narrows the rectum by the surrounding fibrosis which is appreciable on digital examination for at least 18 months postoperatively. This often leads to the passage of frequent pellet-like stools. This type of bowel habit and rectal narrowing frequently settles down over the course of a year and allows the patients to time their bowel actions more satisfactorily. The third important factor is the absence of the continuing dilatation of the anal canal by a large complete prolapse so that there is a reduction in the diameter of the anal canal, although only rarely have we been able to detect any clear quantitative improvement in pelvic electromyograms postoperatively. There is no doubt, however, that elimination of a complete rectal prolapse allows the patient to practise sphincter exercises more effectively and the adjuvant use of faradism appears to re-educate their proprioceptive reflexes and to improve conscious knowledge of when their sphincters are contracting. Pelvic electromyograms after pelvic faradism, however, have not shown any objective improvement in performance.

Subsequent operations for incontinence are difficult to evaluate in this series because of the small numbers involved. A few patients make an early and urgent demand for operation, while others are relieved to be rid of their prolapse, are quite happy to wear a pad to control incontinence, and do not wish to have another operation. Certainly in the present series we have not pressed additional operations on these patients, mainly because we are uncertain of success. The Thiersch operation is useful but it has a number of problems associated with it, viz., faecal impaction, and as many of these patients are constipated, this can present a serious problem. When wire is used it may fracture or cause ulcers. Nylon thread has proved to be more satisfactory.

The most useful operation is the post-anal intersphincteric nylon-floss operation repair described by Parks (1967). Nevertheless, this is not an easy undertaking and there is often delay in wound healing. It is not advocated for minor degrees of incontinence or leakage.

It is also clear, from our experience of 1 case, that colostomy is not necessarily the answer to incontinence.

Lastly, there are a number of patients who might well be benefited by operations for their incontinence. The majority of these patients has declined the operation when the offer has been made, being content to be free of their prolapse. In a small number a further operation was inadvisable as their general health was poor.

EXPERIENCES OF IVALON-SPONGE IMPLANT FOR COMPLETE RECTAL PROLAPSE AT ST. MARK'S HOSPITAL, 1960–70

By J. C. B. PENFOLD and P. R. HAWLEY
ST. MARK'S HOSPITAL, LONDON

SUMMARY

Experience of using Ivalon-sponge implants in 101 patients with complete rectal prolapse at St. Mark's Hospital is reviewed. It is a straightforward operation with minimal complications producing long-term control of the prolapse in 97 per cent of cases.

Of those patients who had been incontinent, satisfactory restoration of continence was achieved in 70 per cent of cases for solid faeces and in 33 per cent for fluid faeces.

Ivalon sponge is a foreign material that only produces moderate fibrosis in the tissues. It persists for at least 6 years in humans.

Complete rectal prolapse is a very disabling but non-lethal condition. Many operations have been devised to cure it but none has been entirely satisfactory. At the present time the Ivalon-sponge implant is being increasingly used throughout Great Britain. This paper reports our experiences using this operation during the years 1960–70.

MATERIALS

One hundred and one patients underwent repair of complete rectal prolapse using an Ivalon-sponge implant (*Fig.* 1). The youngest was 21 years and the oldest 82 years. Thirty patients had had previous surgery for the prolapse, including 14 Thiersch wire or nylon operations, 6 rectosigmoidectomies, 4 Thiersch operations and rectosigmoidectomies, and 6 miscellaneous perineal repair procedures

METHODS

The technique described by Wells (1959) using a 3-mm.-thick piece of polyvinyl alcohol (Ivalon) sponge placed behind the rectum was used. The sponge was perforated and soaked in saline before insertion. It was then attached to both the rectum and the sacrum. Usually one or two non-absorbable 'hitch' sutures were inserted between the mesorectum or lateral ligaments and the lumbosacral disk. Postoperative antibiotics were not given routinely.

Surgical technique varied to a certain extent between surgeons, but we feel that there are several important steps to ensure a successful operation.

The rectum must be mobilized right down to the coccyx posteriorly. Usually only the upper one-third of the lateral ligaments is divided but this should not compromise the posterior mobilization.

Haemostasis must be perfect at this stage. On no account should the Ivalon be inserted before all pelvic bleeding has been completely controlled. The subsequent haematoma would predispose to an infected sponge should any inadvertent contamination occur.

We prefer to insert the sponge with its long axis parallel to the rectum. The caudal extremity of the sponge is tapered a little. Special care is taken to ensure that it is inserted well down behind the rectum so that its lower end extends at least to the tip of the coccyx. The sponge is then fixed firmly by several sutures to the anterior surface of the sacrum. This suture should always be non-absorbable (either nylon or linen thread).

The 'hitch' suture is then performed. Before this was done routinely 1 case developed a complete recurrence of the prolapse in the immediate postoperative period following a bout of coughing. (Fortunately it was possible to replace the rectum in the ward with a long-term satisfactory result.)

The two leaves of the sponge are then wrapped around the rectum making sure that at least 2–3 cm. of the anterior circumference of the rectum remain uncovered (to prevent causing a constriction of the lumen). The leaves of the sponge are then fixed in place with several sutures to the seromuscular layers.

The peritoneum is closed over the Ivalon sponge so that none is left exposed to the peritoneal cavity. Care must be taken here to ensure that the base of the sigmoid mesocolon is not shortened. This would predispose to postoperative sigmoid volvulus as the sigmoid is usually redundant and on a long mesentery in complete rectal prolapse.

RESULTS

Morbidity and Mortality.—Postoperative morbidity occurred in only 6 per cent of cases. One sponge became infected and had to be removed. This followed an attack of acute appendicitis in the immediate postoperative period. The patient had a persistently elevated temperature and lower abdominal pain. At operation 2 months later the Ivalon sponge was found lying in a pool of pus. Another patient developed similar symptoms but had cystitis which responded to antibiotics. Two patients developed wound abscesses that were drained. In neither case was the Ivalon-sponge implant involved.

Two patients developed large-bowel obstruction at the rectosigmoid junction. One settled conservatively, but the other required laparotomy to free a sigmoid loop which was adherent in the pelvis.

There were no operative deaths in these 101 patients.

Follow-up.—Six patients were lost to follow-up, leaving 95 available for review. The period since the operation was from 2 to 12 years, with an average of 6 years. The review was either by examination in the clinic or, if the patient was deemed too elderly for this, by a postal questionnaire. The results refer to the findings at review after July, 1971, except for 10 patients who had died before this time. For these the findings within 6 months of the time of death are used.

Recurrences.—A complete rectal prolapse recurred in 3 of the 95 patients reviewed: 1 at 6 months, 1 at 2 years, and 1 at 4 years postoperatively. Of these, 1 case had a further successful Ivalon-sponge implant as it was felt that at the first attempt the Ivalon sponge had not been placed low enough in the pelvis. Another underwent an anterior resection because he had concomitant diverticular disease and the third refused any further treatment.

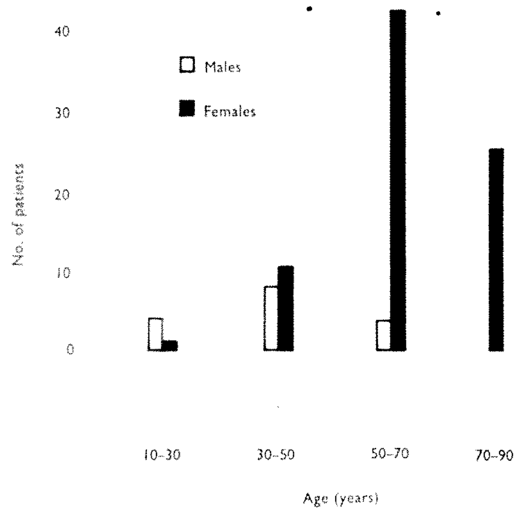

FIG. 1.—The age distribution of 101 patients undergoing an Ivalon-sponge implant for complete rectal prolapse.

Thirty-one of the 95 cases had varying degrees of mucosal prolapse on straining. Ten cases were treated by injection with 5 per cent phenol in arachis oil, 5 by a mucosal strip and ligation operation, 5 by a Thiersch-wire operation, and the rest did not receive any further treatment.

Anal Continence.—All the patients were asked specific questions about continence. Since 10 patients had died and there was insufficient information regarding their continence at the time of death and a further 6 patients had had additional major rectal surgery since the Ivalon-sponge implant, only 79 were reviewed.

Preoperatively 46 patients (58 per cent) had been continent for solid faeces, 31 (38 per cent) for fluid faeces, and 28 (35 per cent) for flatus. After the operation 70 patients (88 per cent) were continent for solid faeces, 47 (59 per cent) for liquid faeces, and 41 (51 per cent) for flatus.

Thirty-seven patients (47 per cent) found no change in bowel function following the operation, 23 (29 per cent) found defaecation more difficult, and only 19 (24 per cent) found it easier.

Postoperatively 46 (59 per cent) continued to take laxatives or suppositories to help to regulate their bowels.

Urinary-bladder Function.—Seventy-two of the 79 patients found no change in micturition following the operation. Only 3 cases found micturition more difficult, although another 4 patients developed stress incontinence.

Patient Satisfaction.—All 79 patients were specifically asked for their opinion of the results of the operation. Sixty-four patients (81 per cent) were very satisfied with the operation. (This highlights the distressing nature of prolapse as many of these patients were still incontinent.) A further 9 patients were satisfied with reservations and 6 were unsatisfied.

Of the latter 6 cases, 5 were completely incontinent and 1 has had a complete recurrence but refuses further surgery.

Failed Ivalon-sponge Operations.—Six patients underwent further abdominal operations as it was considered that the Ivalon-sponge implant had been a failure. Reoperation was for an infected Ivalon sponge in 1 case, for complete recurrence in 2, for severe incontinence in 2, and for alternating incontinence and faecal impaction in 1.

Thus, with the 6 unsatisfied patients at least 12 of the 101 operations were not successes.

EXPERIENCE OF REOPERATING ON PATIENTS WITH IVALON-SPONGE IMPLANTS

Over the past 10 years 7 patients who had had previous Ivalon-sponge implants (some implanted elsewhere) have been reoperated on at St. Mark's Hospital. Because of the natural apprehension about the insertion of a new foreign material into the body we feel that the experiences gained from these operations are of interest.

Infected Ivalon sponges were removed from 2 patients 2–3 months after they had been implanted. One had been implanted at another hospital. In both cases the Ivalon sponge was found lying in a pool of pus and was easy to remove. The cavities were drained. In 1 patient the rectum was inadvertently opened, necessitating a proximal colostomy. The abscess recurred and at re-exploration further fragments of Ivalon sponge were found and removed. Subsequent healing was uneventful. The other case healed uneventfully and the prolapse has not recurred.

Two patients had a Hartmann's operation with bowel resection for intractable incontinence 1–2 years after the Ivalon-sponge implant. In neither case was there much evidence of previous pelvic surgery or increased fibrosis behind the rectum. The mobilization was easy and only fragments of Ivalon sponge were found in the resected specimens.

Three patients had reoperations for incontinence 4–6 years after the original operation. One patient had another Ivalon-sponge implant, 1 case underwent an anterior resection, and the third had an abdominoperineal excision. In all 3 cases the mobilization was easy with little to suggest previous pelvic surgery.

FATE OF THE IVALON SPONGE IN HUMAN TISSUES

Two operative specimens were meticulously examined for evidence of the previous Ivalon-sponge implant: one was removed 2 years after insertion and the other after 5 years. Macroscopically both specimens appeared normal. There was no noticeable thickening of the mesorectum and the Ivalon-sponge implant was not obvious, although on careful dissection fragments were found to be present in both cases. Microscopically, a marked foreign-body giant-cell reaction to the Ivalon-sponge implant was noted but there was only a moderate fibrotic response. The fibrous tissue stopped abruptly at the edge of the sponge. There was no active inflammatory response to the sponge.

DISCUSSION

The Ivalon-sponge implant has given very good results for the control of complete rectal prolapse. This agrees with previous reports on smaller series (Morgan, 1962; Calne, 1966; Kupfer and Goligher, 1970). There is no evidence so far to suggest that there is an increasing recurrence rate with longer follow-up.

However, in many patients the major problem is often incontinence of faeces and flatus, and in these cases the Ivalon-sponge implant is far less successful. Incontinence has been noted previously after other operations for rectal prolapse (Kupfer and Goligher, 1970). About 40 per cent of cases still do not have satisfactory continence after the Ivalon-sponge operation. It is in these patients that further surgery aimed at improving anal function such as a post-anal repair or perhaps a Thiersch nylon operation should be considered.

Technically, repair using an Ivalon sponge is not difficult. It is tolerated well by the patients and the morbidity and mortality are low. The absence of sepsis in the present series following the insertion of a foreign material is very gratifying, especially when a previous report mentions an incidence of 16 per cent (Kupfer and Goligher, 1970).

Reoperation on patients containing previously implanted Ivalon sponge has been surprisingly straightforward. The minimal amount of fibrous tissue found between the sacrum and the rectum in these cases suggests that the success of the operation in controlling the prolapse is not due to fixation of the rectum to the sacrum but rather to a stiffening of the rectum itself, thus preventing rectal intussusception from commencing.

The Ivalon sponge, although it fragments, has been found to persist in human tissues for 5 years. It produces a foreign-body reaction with only moderate fibrosis which is limited to the sponge itself. These observations conflict with previous reports of findings in experimental animals and man (Schofield, 1955; Wells, 1959). These suggest a much greater fibrotic response than we have found. Wells (1959) referred to 'marble busts' when Ivalon sponge was implanted in the mammary region.

There is no evidence of sarcoma formation from the Ivalon-sponge implant in these patients, despite observation of up to 12 years.

Acknowledgements.—We wish to thank the staff of St. Mark's Hospital, London, for permission to study their patients and Dr. Bob Riddell for reviewing the histological sections.

A PROSPECTIVE STUDY OF THE IMMEDIATE AND LONG-TERM RESULTS OF POLYA GASTRECTOMY FOR DUODENAL ULCER

By K. C. McKeown

SENIOR CONSULTANT SURGEON, DARLINGTON MEMORIAL HOSPITAL, AND THE FRIARAGE AND RUTSON HOSPITALS, NORTHALLERTON

SUMMARY

The results of a prospective study of Polya-type gastrectomy in 800 cases of duodenal ulcer are recorded.

The series is an entirely personal one in which case selection and operative technique were standardized, though in the assessment of the results the opinions of many observers have been collated.

The results in the early years are recorded and the effects of revision surgery noted.

Special attention has been paid to the nutritional state after operation and to the long-term metabolic consequences 10–20 years after gastrectomy.

The immediate and long-term results of gastrectomy are compared and contrasted with those obtained by vagotomy and drainage.

THE surgical treatment of duodenal ulcer has occupied the attention of surgeons for over half a century. In spite of the enormous number of clinical and laboratory investigations no operation has emerged as the ideal procedure for all cases and it seems likely that none exists.

The undoubted success of simple gastro-enterostomy in the Moynihan era became clouded by the high incidence of stomal ulceration and the operation fell into disrepute. The problem of recurrent ulceration was vastly diminished by the introduction of the more formidable procedure of partial gastrectomy, and for many years this operation held pride of place in the surgical treatment of duodenal ulcer. The known post-prandial symptoms occurring in a small proportion of cases after gastrectomy were regarded as a small price to pay for the relief of pain and the removal of the hazards of haemorrhage and perforation. Disturbing reports of loss of weight, the high incidence of anaemia and of pulmonary tuberculosis, and the more remote sequelae of metabolic bone disease after gastrectomy have, however, directed attention to the more conservative measures of vagotomy and drainage.

Now that vagotomy has been in vogue for 20 years and its immediate and long-term consequences are more fully known it would seem appropriate at this time to make a further report on a prospective study of partial gastrectomy which was started in 1950 and which has continued to the present time.

The first report of this prospective study of the results obtained in 1000 cases of gastrectomy for peptic ulcer (McKeown, 1962) dealt mainly with the results obtained in the early years after operation. The present report is more comprehensive in that it not only records the immediate results but also makes a special study of the long-term metabolic consequences of gastrectomy 10–20 years after operation for duodenal ulcer.

This series is a large and entirely personal one in which all the cases have been examined, investigated, assessed, and operated on by one surgeon, and differs from that of Goligher and others (Goligher, Pulvertaft, and Watkinson, 1964; Goligher, Pulvertaft, de Dombal, and others, 1968) in which ten surgeons in different hospitals participated in the Leeds/York trial, and from that of Cox (1968) in which the recorded results were those of the Surgical Staff of the Western General Hospital, Glasgow.

THE PROSPECTIVE STUDY

This prospective study was started in 1950 in the Northallerton and Darlington area which is situated midway between the teaching centres at Leeds and Newcastle. In this area population changes in both the rural and urban districts were much less frequent than those in the big cities and in consequence follow-up was much easier.

Table I.—Indications for Surgery for Duodenal Ulcer

Absolute	*Relative*
Pyloric obstruction	A 5-year period of ulcer dyspepsia
Dangerous bleeding	Perforation
	Haematemesis or melaena

From the outset the intent was to make an objective assessment of the results of partial gastrectomy in peptic ulcer and therefore certain clinical features had to be standardized. It was essential that the criteria for selection of cases for surgery should be clearly defined and adhered to, that the operative technique be unvaried, and that the pre- and post-operative management should be the same in all cases. The follow-up was frequent and continuous, and though the series was an entirely personal one, in reviewing and grading the results the opinions of the patient, his relatives, and his general practitioner have all been collated, as well as the views of the various surgical registrars who have served in the units.

Criteria of Case Selection.—Though such factors as age, sex, social class, and individual personality should be taken into consideration in case selection for surgery, the system adopted in this trial was based purely on clinical features and the level of gastric acidity did not influence the decision to operate or modify the extent of gastric resection. Indications for operation were considered to be either absolute or relative as shown in *Table I.*

Absolute indications for gastrectomy were organic pyloric obstruction or dangerous haemorrhage. The former indication called for operation when the fluid and electrolytic balance had been restored, while dangerous bleeding was treated by emergency gastrectomy. Dangerous bleeding was considered to be present in the following circumstances:—

1. Catastrophic bleeding when it was difficult to replace blood-loss and maintain an adequate blood-pressure.

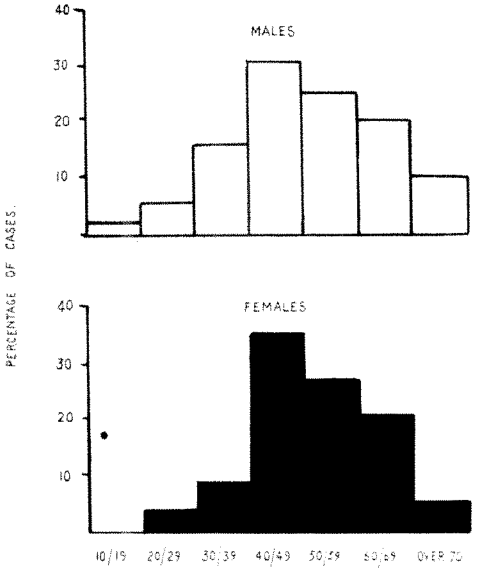

FIG. 1.—The age distribution of 648 men and 152 women in whom Polya gastrectomy for duodenal ulcer was performed.

2. Bleeding of lesser severity which continued or recurred while the patient was still in hospital.

3. Severe bleeding in patients of over 50 years who had long-standing proved duodenal ulcer.

Relative indications for surgery were based on three features: a 5-year history of dyspepsia, perforation, or bleeding. If any two or more of these clinical features were present the patient was considered suitable for operation. Also a patient who had sustained two perforations or two episodes of bleeding was considered suitable for surgery as well as those patients who had had persistent or recurrent dyspepsia for 10 years.

Because of the strict criteria of case selection most of the cases who were submitted to operation were of middle age with a peak incidence for both sexes in the decade 40–49, as shown in *Fig.* 1. In spite of the bad reputation associated with the operation in young subjects partial gastrectomy was carried out in these cases provided that the clinical criteria were present. Similarly, no cases were refused operation on the grounds of advanced age if the criteria were fulfilled, provided that the patients were fit for anaesthesia and not likely to die in the near future from concomitant disease.

Type of Operation.—At the commencement of this study it was intended to use with equal frequency either the Polya-type operation with a valved or full-length stoma or the Billroth-I operation. Experience soon showed that the high recurrence rate after the Billroth-I operation of 15·7 per cent (8 out of 5 cases) precluded its further use, while the full length stoma resulted in a higher incidence of post prandial symptoms and it too was abandoned.

The results described in this paper are thos obtained when a modified Polya operation was used This standardized operation removed the distal hal

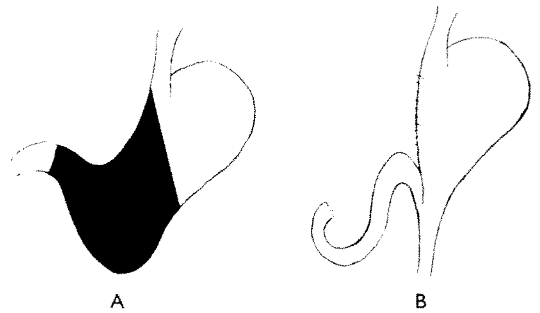

FIG. 2.—The operative procedure for duodenal ulcer. A, The complete excision of the lesser curvature, showing the amount of stomach removed at the partial gastrectomy. B, The reformation of the lesser curve and the valved gastrojejunal anastomosis.

of the stomach together with the entire lesser curvature up to the gastro-oesophageal junction. The lin of section on the greater curvature stopped at th level of the first vasa brevia so that in all abou two-thirds of the gastric tissue were removed, a shown in *Fig.* 2. The lesser curvature was suture to form a long tapering stomach remnant which wa anastomosed to the jejunum at a distance of, o average, 13 cm. from the duodenojejunal flexure. I obese patients omentum was resected to enable th afferent loop to be kept short and to prevent the pul of a heavy fat-laden omentum on the gastrojejuna anastomosis. In all the cases the pyloric end of th stomach was removed and in no case was the Bancrof or Plenk manœuvre employed. All cases had a drai inserted down to the point of duodenal closure t minimize the effects of unpredictable duodena stump leakage.

Method of Follow-up.—Each patient was issue with a *pro forma* on which all the relative clinica details were recorded with special reference to th operative findings and the postoperative progress The frequent review examinations during the firs postoperative year were regarded as a period o supervision. No attempt was made to grade th results until the end of this period as it was foun that the transient discomforts of the first few week may relegate some patients to a low grading, while i others initial success may become clouded by th onset of symptoms several months after operation After the initial grading patients were reviewe annually and were up-graded or down-graded wit the remission or development of post-gastrectom symptoms over a period of up to 20 years, so tha the elapse of time played a part in the grading o results.

Grading of Results.—Patients were placed in one of three categories:—

Grade I: Symptom Free.—In this grade the patient were able to eat, drink, and smoke without restraint and had been able to return to the heaviest duties on a farm or in a factory. This group corresponds to the 'excellent' grading of the American Society of Gastro-enterologists and to Visick's (1948a, b) grade 1.

Grade II: Satisfactory.—Patients in this category expressed complete satisfaction with the results of operation, but on inquiry would reluctantly admit to occasional mild dyspepsia. This grading corresponds to the American Society of Gastro-enterologists' grading 'good' and to Visick's grade 2.

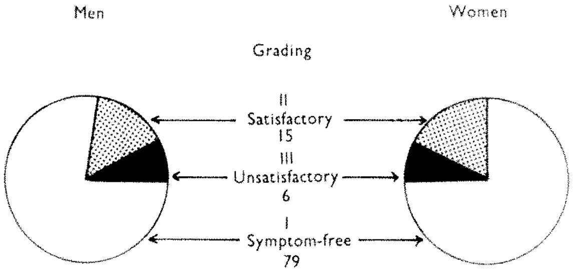

FIG. 3.—The results of gastrectomy in 800 cases of duodenal ulcer. The unsatisfactory group represents 6 per cent of the entire series. In the symptom-free grading men show marginally better results than women. (All the figures are percentages.)

Grade III: Unsatisfactory.—All the patients who could not be placed in grades I or II were included in this category, even though some patients felt that they had benefited and that the operation was well worth while (Visick's grade 3S). Also included in this category were those patients who developed recurrent ulcer, persistent post-gastrectomy symptoms, or severe nutritional disturbance (Visick's grade 3U and grade 4). Of these latter outright failures, a proportion have been improved by further operative procedures and have subsequently been upgraded.

MATERIAL AND DATA

The series consisted of 800 cases of duodenal ulcer who were operated on in the period 1950 to 1960 and who had not previously had any gastric operation other than the suture of a perforated ulcer. Sixty other cases (51 men and 9 women) who had associated gastric ulcers were excluded from this review. Of the 800 cases, 648 were men and 152 women.

RESULTS OF GASTRECTOMY FOR DUODENAL ULCER

Using the system of grading as outlined above, it was found that 79 per cent of all the patients could be included in grade I. Male patients fared better than females in that 80 per cent of the men as against 76 per cent of the women could be placed in grade I, as shown in *Fig.* 3.

Fifteen per cent of cases (14 per cent of the men and 18 per cent of the women) fell into grade II. The incidence of patients in the unsatisfactory grade III was the same in both sexes (6 per cent) but the cause of failure was different. In the male patients recurrent ulcer and a higher operative mortality accounted for over half of the subjects in this category, while in the women post-prandial symptoms were the cause of failure in the great majority of cases, as shown in *Fig.* 4.

THE SEQUELAE OF POLYA GASTRECTOMY

The sequelae of gastrectomy may arise from the technical problems and difficulties of the operative procedure, from anatomical alterations involved in gastrojejunal anastomosis, or as a result of alterations in the physiology of the digestive tract. As such, the consequences of gastrectomy may be immediate, deferred, or long term, and have been considered under the following headings:—

1. Mortality.
2. Recurrent ulcer.
3. Post-gastrectomy syndromes.
    - *a.* Dumping syndrome.
    - *b.* Bilious vomiting ('afferent-loop syndrome').
    - *c.* Mixed post-gastrectomy syndromes.
4. Oesophageal stenosis.
5. Malabsorption syndromes.
    - *a.* Weight changes.
    - *b.* Post-gastrectomy anaemia.
    - *c.* Post-gastrectomy bone disease.
    - *d.* Plasma-protein levels.
6. Pulmonary tuberculosis.

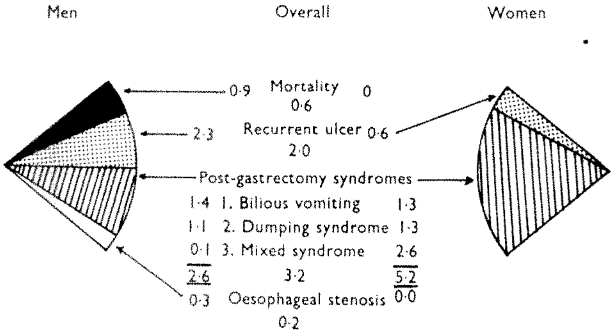

FIG. 4.—The overall failures of gastrectomy are shown together with a comparison of the causes of failure in men and women. Recurrence and post-gastrectomy syndromes are the causes of failure of gastrectomy in men, while in women post-gastrectomy syndromes account for almost all the unsatisfactory results, and recurrent ulcer is rare. (All the figures are percentages.)

The results of the analysis of the failures in the first 5 years after gastrectomy are depicted in *Fig.* 4.

1. **Mortality.**—The estimation of mortality was simple and exact. All the cases dying in hospital after operation were included, even though the cause of death was not directly associated with the ulcer or the operation performed for its cure. An analysis of the causes of death is presented in *Table II.*

Of a total of 778 cases undergoing elective gastrectomy, 6 patients died, giving a mortality figure of 0·7 per cent. In considering this figure it should be noted that there was no discrimination against the poor-risk patient. In the early part of the series a high proportion of the patients were elderly, in a very poor general condition, and suffering from long-standing penetrating ulcers. When this hard core of poor-risk patients had been dealt with the death-rate fell, and in 400 consecutive patients there was not a single operative death.

In view of many considerations, both clinical and administrative, only patients with dangerous haemorrhage were subjected to emergency gastrectomy.

Of 22 cases operated on as emergencies for dangerous bleeding, 6 patients died. This mortality figure of 22·7 per cent emphasized the increased hazards of non-elective operation, especially in the old and the unfit.

Of the fatalities, all 12 occurred in male patients who with 1 exception were in middle life or old age. Two patients died from persistent oozing from the gastric remnant and were considered to be suffering from afibrinogenaemia (*Cases* 2 and 12[*]), while a third died of a sudden massive haemorrhage from an oesophageal varix ulcerated by the indwelling nasogastric tube (*Case* 1). One obese bronchitic man of 57 (*Case* 8) died from peritonitis due to duodenal stump leakage 5 days after operation. *Case* 3 died of hepatic failure 13 days after operation, while the remaining cases died of some cardiac or pulmonary factor not directly related to the operation, as shown in *Table II*.

Table II.—THE CLINICAL DETAILS OF 12 CASES WHO DIED AFTER GASTRECTOMY

CASE	AGE AND SEX		CAUSE OF DEATH	TIME OF DEATH AFTER OPERATION (day)	COMMENTS
1. R. E. B.	50	M.	Rupture of oesophageal varix	3	Ulceration of oesophagus due to nasogastric tube
2. E. B. W.	63	M.	Persistent bleeding	22	Afibrinogenaemia
3. D. M. D.	71	M.	Liver failure	13	—
4. W. H. D.	56	M.	Coronary thrombosis	5	—
5. T. J. D.	61	M.	Pulmonary embolus	10	Emergency gastrectomy. Haemorrhage
6. J. F.	72	M.	Renal failure	9	Emergency gastrectomy. Prolonged hypotension. P vious ischaemic heart disease
7. M. McG.	72	M.	Bronchopneumonia and chronic pyelonephritis	19	Emergency gastrectomy. Long history of pyelonephri
8. W. C.	57	M.	Peritonitis due to duodenal stump leak	5	Extreme obesity and poor chest condition
9. M. L.	43	M.	Pulmonary embolus	21	Wound sepsis
10. B. C.	22	M.	Pulmonary embolus	6	Emergency gastrectomy. Bleeding
11. C. G.	50	M.	Irreversible shock	Immediately	Emergency gastrectomy. Very severe haemorrhage fr gastroduodenal artery
12. A. N. O.	80	M.	Persistent bleeding	20	Emergency gastrectomy. Transfused with 34 bottles blood over 20 days

2. Recurrent Ulcer.—An analysis of the cases of stomal ulcer is presented in *Table III*. Sixteen out of 800 cases developed stomal ulcer, giving an overall incidence of 2 per cent. Of the 648 male patients, 15 (2·3 per cent) developed stomal ulcer, but of 152 females, only 1 case (*Case* 16) had recurrent ulceration (0·6 per cent).

Thirteen of these cases presented with recurrent dyspepsia, of which 5 also suffered from haemorrhage and 1 from perforation. Of the 2 cases who denied any history whatever of postoperative dyspepsia, 1 case (*Case* 7) had recurrent haemorrhage while another case (*Case* 16) had a perforation. A feature of note was the tendency for the early onset of stomal ulcer. In 2 patients symptoms occurred within a month of operation, while in several other cas symptoms developed within 15 months. In 3 cas stomal ulcer occurred after 2 years, and in only instances (*Cases* 7 and 10) was the onset delay for 5 and 7 years respectively. No age-group w immune from recurrent ulcer, but when the numb of cases operated on in each decade is taken in consideration, as shown in *Fig.* 1, it was found th young patients were more liable to recurrent ulc In those operated on between the ages of 20 and the incidence of stomal ulceration was 4·8 per cer but in the 30–39 age-group the incidence dropp to 2·2 per cent with similar falls in succeedi decades.

Of 7 cases of stomal ulcer submitted to simp re-gastrectomy, 3 cases had further ulceration whi in 2 cases was subsequently successfully treated revision gastrectomy combined with vagotom The remaining case (*Case* 4), who had moved out the area, subsequently developed a gastrojejunocol fistula which has been successfully treated by excisi of the fistula combined with vagotomy. Because of t relative failure of re-gastrectomy all subseque cases of stomal ulcer had revision gastrectomy co bined with truncal vagotomy. Of the 8 cases treated, none had further ulceration but 2 cas (*Cases* 9 and 15) have suffered from persiste diarrhoea. In none of these cases of recurrent ulc was a Zollinger-Ellison tumour discovered thou this was specifically looked for. Of the 16 cas submitted to further surgery, 4 have been upgrad to grade I, 9 are in grade II, 2 have remained grade III, while 1 other patient was found to suffering from cirrhosis of the liver and was in co sequence not put in any grade.

Post-gastrectomy Bleeding not due to Stomal Ulc —In addition to the 16 cases of proved ston ulcer there were 7 other patients who we

suspected of suffering from this condition. Five o these presented with histories of melaena, 1 witl haematemesis, and 1 with bleeding and abdomina pain. In none of these cases could stomal ulceratio be demonstrated after most careful radiological an gastroscopic examinations, while the secretion test in these subjects showed low acidity not consisten with recurrent ulceration.

Details of this group of cases are shown in *Table IV* In 3 patients (*Cases* 1, 3, and 5) bleeding was attributed to the taking of aspirin in an acute febril illness. *Case* 4, a heavy drinker, suffered fron gastritis and jejunitis, but in 2 other cases the caus of bleeding was not known. One case (*Case* 7 showed a marked tendency to bleed from mino trauma, and the melaena from which he suffere was thought to be associated with a haemorrhagi state.

It might be argued that in spite of persistentl negative radiological and gastroscopic examination these 7 patients did in fact have a stomal ulce Were this contention to be accepted, there woul then be 23 cases of proved or suspected stoma ulcer out of a total of 800 cases, an incidence of 2· per cent.

Recurrent Ulcer in the Gastric Remnant.—On patient, a woman of 64 years, had a Polya gastrectom for duodenal ulcer and made a good recovery. On year later she was admitted in emergency wit severe haematemesis and diffuse peritonitis. She wa unfit for laparotomy and died a few hours afte admission to hospital. At the post-mortem examination she was found to have a large gastric ulce measuring 3·8 × 2·5 cm., which was situated in th gastric remnant well away from the stoma. Th gastrojejunal anastomosis was entirely normal bu bleeding had taken place from the gastric ulcer, whic had also perforated.

3. Post-gastrectomy Syndromes.—A sur prisingly high proportion of cases could eat an drink without restraint, even in the early weeks c convalescence. On the other hand, there were thos who experienced a wide range of post-cibal symptom of which a sensation of distension after a full mea was perhaps the most common complaint. No specia significance was attached to these discomforts in th early weeks or months after operation, but attentio was focused on those whose symptoms had persiste or had developed for the first time a year afte operation.

A general survey of the series shows that of th 800 cases, 25 patients (3·2 per cent) had persisten post-gastrectomy symptoms. The incidence i women was twice as high as that in men, and of 15 female patients, 8 (5·2 per cent) were affected, whil of 648 males, only 17 (2·6 per cent) were similarl troubled. These results are outlined in *Fig.* 4.

Persistent post-gastrectomy symptoms thoug variable and not always precise and clear cut wer considered under three headings according to th predominant feature:—

a. Dumping syndrome.
b. Bilious vomiting ('afferent-loop syndrome').
c. Mixed post-gastrectomy syndromes.

In this connexion it should be noted that thos patients who experienced persistent fullness afte a very heavy meal and who may be considered to b suffering from the 'small stomach syndrome' were included in grade II. If, however, these symptoms were severe or associated with other post-cibal syndromes, such cases were categorized as failures of gastrectomy and placed in grade III.

was greatly improved by narrowing of the gastro-jejunostomy stoma.

Four cases were managed conservatively by modification of their diet and the avoidance of drinking sweetened fluids especially at meal times. Within these limitations they were able to continue in their usual employment but were, however, considered only moderately successful and were included in grade II, partly because of the necessity of imposed dietetic restriction but also because of associated disease, as shown in *Table V*. Of these 4 cases, *Case* 1 subsequently had a cholecystectomy for gall-stones and thereafter a cystectomy for carcinoma of the bladder. *Case* 2 developed portal hypertension, while *Case* 3 suffered recurrent intestinal obstruction due to adhesions. *Case* 6 was difficult to assess as he suffered from pain due to coronary disease.

Of 4 other cases in which the Polya gastrectomy was converted to one of Billroth-I type, 2 cases (*Cases* 7 and 8) were completely cured and upgraded to grade I, while *Case* 5, though much improved, suffered from loss of weight and anaemia. The remaining patient (*Case* 9) was an interesting failure. This 49-year-old woman suffered from severe vasomotor symptoms associated with diarrhoea which were much improved by the conversion operation. Later, however, she developed ulceration at the gastroduodenal anastomosis. When submitted to re-gastrectomy and a classic Billroth-II operation was carried out the dumping syndrome recurred. Vagotomy combined with a Billroth-I operation was advised, but the patient understandably enough was

Table V.—THE CLINICAL DETAILS OF 9 CASES SUFFERING FROM THE PERSISTENT DUMPING SYNDROME

CASE	AGE AND SEX	TYPE OF OPERATION	TIME OF ONSET	MOST SEVERE SYMPTOMS	TREATMENT	RESULT	COMMENT
. A. W.	47 M.	Polya	6 wk.	Vasomotor symptoms	Conservative	Cleared up in 1 yr. Grade II	Subsequent cholecystectomy for gall-stones and total cystectomy for carcinoma of bladder
. T. W. J.	45 M.	Polya	2 mth.	Sweating, palpitations, lacrimation, and severe hunger	Conservative	Cleared up after 1 yr. Grade II	Also had portal hypertension
. O. H.	27 M.	Polya	2 mth.	Vasomotor symptoms	Conservative	Cleared up after 15 mth. Grade II	Had intestinal obstruction due to adhesion on eleventh postoperative day. Lost 1½ st. but then slow increase in weight
. T. S. A.	26 M.	Polya	3 mth.	Sickness, desire to defaecate 10 min. after food, and faintness 2 hr. after meals	Narrowing of stoma	Improved after operation Grade I	Hypoglycaemia 2 hr. after food
. A. L.	40 F.	Polya	1 mth.	Vasomotor symptoms	Conversion to Billroth-I	Much improved Grade II	Anaemia and loss of weight
. J. F.	45 M.	Polya and valve	4 wk.	Sweating, palpitations, and weakness	Conservative	Cleared up in 1 yr. Grade II	Has now developed coronary and arterial disease
. W. B.	64 M.	Polya and valve	4 wk.	Listlessness and headache	Conversion to Billroth-I	Cured Grade I	Gained 1½ st. after conversion operation
. H. A. S.	49 M.	Polya and valve	4 wk.	Sweating, palpitations, and weakness	Conversion to Billroth-I	Cured Grade I	Nervous factors
. R. S.	49 F.	Polya and valve	1–2 mth.	Fullness, sickness, and palpitations. Diarrhoea	Conversion to Billroth-I Conversion of Billroth-I to Billroth-II	After initial improvement developed stomal ulcer with stenosis Dumping became severe again after the second conversion operation	Unwilling to undergo further surgery 'Gastric cripple'

a. Dumping Syndrome.—In this group were included those patients whose post-prandial symptoms were predominantly vasomotor in type and who soon after a meal experienced a variety of symptoms such as flushing, sweating, fainting, palpitations, lethargy, giddiness, or muscular weakness. An epitome of the clinical details of such patients is shown in *Table V*.

Of the 800 cases who were submitted to a modified Polya gastrectomy, 9 developed the dumping syndrome which persisted, an overall incidence of 1·1 per cent. Two women (1·3 per cent) and 7 men (1·09 per cent) suffered from this complaint (*Fig.* 4).

Only on rare occasions did the symptoms develop while the patient was still in hospital and in the majority of cases dumping was first experienced 4–6 weeks after operation, though in 1 case (*Case* 4) the onset of symptoms was delayed for 3 months. Some of the classic vasomotor symptoms were present in all the cases, but 1 case (*Case* 2) had severe lacrimation and hunger pains immediately after food, while in *Case* 4 symptoms of 'early' dumping were also associated with sweating and faintness 2 hours after food which were attributed to hypoglycaemia. This patient, who was considered to be suffering from both 'early' and 'late' dumping, unwilling to undergo further surgery and has been considered as a total failure and regarded as a 'gastric cripple'.

b. Bilious Vomiting ('Afferent-loop Syndrome').—Nine men and 2 women complained of bilious vomiting, an incidence in both sexes of 1·4 per cent.

Table VI.—THE CLINICAL DETAILS OF 11 CASES SUFFERING FROM BILIOUS VOMITING

CASE	AGE AND SEX	TYPE OF OPERATION	TIME OF ONSET	SYMPTOMS	TREATMENT	RESULT	COMMENT
1. M. W.	36 M.	Polya	3 yr.	Vomits food and bile	Conservative	Improved Grade II	—
2. J. M.	54 M.	Polya and valve	3 mth.	Biliary regurgitation before breakfast	Conservative	Grade III	—
3. L. F.	46 M.	Polya and valve	6 wk.	Regurgitation when lying down	Conversion to Billroth-I	Grade I	Satisfactory
4. C. B.	53 F.	Polya and valve	3 wk.	Vomits bile	Conservative	Awaiting conversion operation	Hysterical attack
5. H. P.	55 M.	Polya and valve	3 wk.	Vomiting of food and bile	Laparotomy for obstruction	Cured Grade I	Had myositis oss ficans extendir into stoma
6. R. J. P.	58 M.	Polya and valve	4 wk.	Vomiting bile 1 hr. after food	Division of adhesions	Poor Grade III	Had burst abd men. Folic-ac deficiency
7. M. H.	59 M.	Polya and valve	4 wk.	Biliary regurgitation before breakfast. Pain in left hypochondrium	Suspension of afferent loop Conversion to Billroth-I	No improvement Cured Grade II	Weight-loss Marked weight-gain
8. H. B.	58 M.	Polya and valve	8 yr.	Vomits bile, occasionally bile and food	Division of adhesions of afferent and efferent loops	Improved Grade II	Conversion op ation being cc sidered
9. E. H.	38 M.	Polya and valve	15 mth.	Bilious vomiting	Conversion to Billroth-I	Cured Grade I	Increase in wei
10. D. P.	34 M.	Polya and valve	2 mth.	Vomits bile ¾ hr. after food	Conversion to Billroth-I	Cured Grade I	Increase in wei
11. E. H.	44 F.	Polya and valve	2 mth.	Vomits bile ½ hr. after food	Conversion to Billroth-I Conversion to Billroth-II	Narrowing of stoma and recurrent ulcer Poor	Loss of weight Anaemia and di rhoea; chronic psychotic (depressive); 'gast cripple'

The pattern of bilious vomiting varied from case to case, as outlined in *Table VI*. In 2 patients (*Cases* 1 and 7) vomiting of clear bile occurred on rising first thing in the morning, while in *Case* 3 biliary regurgitation took place when the patient lay down. Three patients noted the vomiting of bile and food ½–1 hour after a meal, while in the remainder of cases vomiting of bile and food occurred at irregular intervals. A characteristic feature of some cases was the ability to eat a full meal immediately after being sick and to experience no further symptoms. An epitome of the clinical details is presented in *Table VI*.

The onset of biliary vomiting occurred 4–12 weeks after operation in 8 patients, while in 3 others (*Cases* 1, 8, and 9) symptoms did not develop for from 1 to 8 years.

In 3 cases biliary vomiting was due to obstruction of the afferent loop (*Cases* 5, 6, and 8). One of these patients (*Case* 5) had a most unusual condition of calcification in the abdominal wound, which extended down to the site of the gastrectomy stoma and strikingly resembled myositis ossificans. In *Case* 6 the cause of obstruction was adhesions contribute to by the fact that this patient had a wound dehiscenc after operation.

Three of the patients were treated conservativel but of these, 1 case, a hysterical woman of 35 year who formerly refused operation, now feels that th symptoms are severe enough to warrant furth surgical treatment. Suspension of a rather depende afferent loop failed to cure *Case* 7, but with co version of the Polya operation to one of Billroth type the symptoms were cured. Of 4 other cas who had the conversion operation, 3 (*Cases* 3, 9, an 10) were so improved that they were promoted grade I, but *Case* 11 was an interesting failu This 44-year-old woman developed bilious vomiti 8 weeks after operation of such severity that a co version operation was carried out soon after t original procedure. The patient then develope stomal ulceration with narrowing of the gastr duodenal anastomosis. A further operation w carried out and a Billroth-II type of anastomos was performed. This patient then developed pe sistent diarrhoea and became anaemic. She was known depressive psychotic who had failed respond to drug or electroconvulsive therapy. It w considered in retrospect that insufficient attenti had been given to the psychiatric state befo operation and she is now regarded as a 'gast cripple'.

Review of the treatment given to these patients, as outlined in *Table VI*, shows that half of the group has been upgraded as the result of revision surgery.

c. Mixed Post-gastrectomy Syndromes.—Five patients suffered from post-prandial discomforts in which the symptoms formed a complex of dumping, bilious vomiting, and the 'small-stomach syndrome', each feature contributing equally to the patient's discomfort. The clinical details of these 5 cases, which represent 0·6 per cent of the total series, are outlined in *Table VII*. Four of these patients suffering from mixed post-gastrectomy syndromes were middle-aged women, but 1 case was a young man of 29 years.

Table VII.—THE CLINICAL DETAILS OF 5 CASES WHO DEVELOPED MIXED POST-GASTRECTOMY SYNDROMES

CASE	AGE AND SEX	TYPE OF OPERATION	PRESENTING SYMPTOMS	TIME OF ONSET	WEIGHT CHANGES	TREATMENT	RESULT	COMMENT
1. L. H.	44 F.	Polya	Fullness and flushing after food Eructations of bile	2 wk. 2 mth.	Gain of 7 lb.	Conversion to Billroth-I	Marked improvement Grade III	Post-gastrectomy anaemia
2. E. M.	49 F.	Polya with valve	Pain and fullness after food; bilious vomiting	2 mth.	Gain of 1 st. 7 lb.	Conversion to Billroth-I	Some improvement Grade II	Emotional factors
3. R. D.	57 F.	Polya with valve	Weakness and giddiness Bilious vomiting twice a week	2 mth. 6 mth.	Loss of 3 st.	Conservative (did not want further operation as she was pain-free)	Grade III	—
4. C. D. H.	29 M.	Polya	Faintness and weariness Bilious vomiting	2 mth. 9 mth.	Loss of 2 st.	Narrowing of stoma Conversion to Billroth-I	Bile vomiting continued Much improved Grade II	Gained 2 st.
5. R. G.	43 F.	Polya with valve	Faintness after food Dyspepsia and bilious vomiting	3 mth. 4 yr.	Gain	Division of adhesions Conversion to Billroth-I	No improvement Improved	Mucosal prolapse at stoma

In 4 cases the Polya gastrectomy was converted to a Billroth-I type, with considerable improvement of the symptoms in all the cases. One of the patients (*Case* 1) developed post-gastrectomy anaemia and therefore has subsequently been downgraded to grade III. Of these 4 cases, 2 had had earlier operations; 1 for narrowing of the gastrojejunostomy stoma (*Case* 4) and 1 for the division of adhesions (*Case* 5), but with no amelioration in symptoms in either case. Both were much improved by the conversion operation. *Case* 5 was of special interest in that mucosal prolapse at the gastrojejunal stoma was thought to be a factor in producing her post-gastrectomy symptoms.

As can be seen from *Table VII*, revision surgery only allowed 2 of the 5 patients to be upgraded from grade III to grade II.

It is interesting to note that 2 female patients who had the Polya operation converted to one of Billroth-I type developed ulceration at the site of the gastro-duodenal anastomosis, thus further emphasizing the unsuitability of Billroth-I operation for duodenal ulcer.

4. **Oesophageal Stenosis.**—Two cases developed dysphagia 3 weeks after operation which was found to be due to an inflammatory condition of the lower end of the oesophagus. A full description of these cases has already been recorded (McKeown, 1958). In each case there was a previous history of oesophageal reflux, and though in both patients operation had produced complete achlorhydria it was felt that they were suffering from reflux oesophagitis. The *p*H of the gastric contents ranged from 6·8 to 7·0, at which hydrogen-ion concentration peptic digestion is minimal and therefore unlikely to cause inflammatory changes in the lower oesophagus. On the other hand, after Polya gastrectomy alkaline duodenal and jejunal contents with high tryptic activity may enter the stomach remnant, and if oesophageal reflux occurred may cause 'tryptic oesophagitis' with resulting stenosis. On these premisses both patients had the Polya operation converted to one of Billroth-I type and in each case a cure was obtained. Since an indwelling nasogastric tube was employed after the second operation as well as after the first it was thought that the presence of the tube did not play any major part in the production of the oesophageal stenosis, as has been suggested by Bingham (1958).

Results of Revision Surgery.—Of a total of 43 patients placed in the unsatisfactory grade III because of recurrent ulcer, post-gastrectomy syndromes, or oesophageal stenosis, 35 patients had a further operation and 8 cases were treated conservatively either because of concomitant disease or because the patient felt that the symptoms were not severe enough to warrant further surgery. Of the 16 cases who suffered from recurrent ulcer, revision gastrectomy with or without vagotomy eradicated this complication in 14 cases but only 3 of them could be upgraded to grade I. Eleven patients were improved sufficiently to place them in grade II, while the remaining 2 cases stayed in grade III, one because of persistent dyspepsia due to suspected stomal ulceration and the other because of post-vagotomy diarrhoea (*Table III*).

Seventeen of the 25 patients with persistent post-gastrectomy syndromes were submitted to further surgical procedures as outlined in *Tables V*, *VI*, and *VII*. Of 11 male patients submitted to reoperation, 7 were upgraded to grade I, 3 grade II, while 1 case remained in grade III. Revision surgery in 6 female patients enabled 3 to be recategorized as grade I, 1 placed in grade II, while the remaining 2 subjects were dismal failures and were designated as 'gastric cripples'.

Both cases of oesophageal stenosis were cured by conversion of the Polya gastrectomy to one of Billroth-I type and were appropriately upgraded.

As the result of revision surgery in 35 of the 43 cases in the unsatisfactory grade III, the percentage of men in this category was reduced from 6 to 1·9 per cent and that of women from 6 to 3·9 per cent. The results of revision surgery are illustrated in *Fig.* 5.

5. **Malabsorption Syndromes.**—Though the primary objective of gastrectomy in the surgical treatment of duodenal ulcer is to diminish the secretion of acid-pepsin, the Polya operation has certain other inevitable consequences. The gastric reservoir is diminished, the regulating mechanism of the pyloric sphincter is abolished, and food is directed from the duodenal circuit and from the first 10–15 cm. of the jejunum. As the result of these factors the digestion of protein, fat, and carbohydrate may be significantly impaired with changes in the nutritional state, as reflected in possible weight-loss. In addition, alteration in the *p*H of the upper intestinal contents, as well as the consequent changes in the bacterial flora, may affect the absorption of iron, vitamin B_{12}, and calcium so that anaemia and metabolic bone disease may occur.

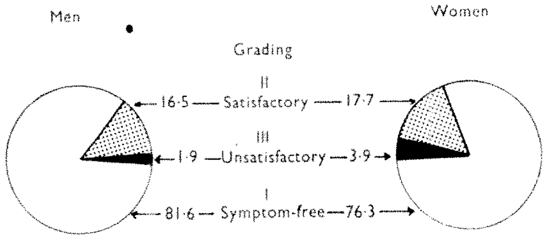

FIG. 5.—The grading of the results of revision surgery after Polya gastrectomy for duodenal ulcer.

a. Weight Changes.—Estimation of weight changes after gastrectomy are hampered by the fact that many patients are overweight at the time of operation as the result of prolonged medical treatment with a milk diet and a high-carbohydrate intake. On the other hand, those suffering from pyloric stenosis may be grossly underweight because of poor food intake and as the result of vomiting and dehydration before operation.

In spite of these known disadvantages, pre- and postoperative weight measurements have been taken and annual records have been made of the weight changes for 5 years after operation. Of 294 patients, 248 (78 per cent) had gained weight 1 year after operation and 44 (12 per cent) had lost weight, while in the remaining 10 per cent the weight remained unchanged. These findings are illustrated in *Fig.* 6.

On further analysis it was shown that the average preoperative weight of those who gained weight was 136 lb. One year after operation the average weight increase in these patients was 15 lb., followed by a further increase of 7 lb. in the second postoperative year. Of the 12 per cent who lost weight, the average preoperative weight was heavier at 151 lb., and the major loss was in the first postoperative year when on average the patients lost 17 lb. There was, however, a tendency for these latter patients t recover weight over the next 4 years. The results o these weight studies are shown in *Fig.* 7.

b. Post-gastrectomy Anaemia.—In the long-ter follow-up all the patients who had had a gastrectom 15–20 years previously had routine estimations of th haemoglobin level, as well as of the serum iron serum vitamin B_{12}, and serum folic acid. In all 116 cases were examined, of which 96 were men an 20 were women.

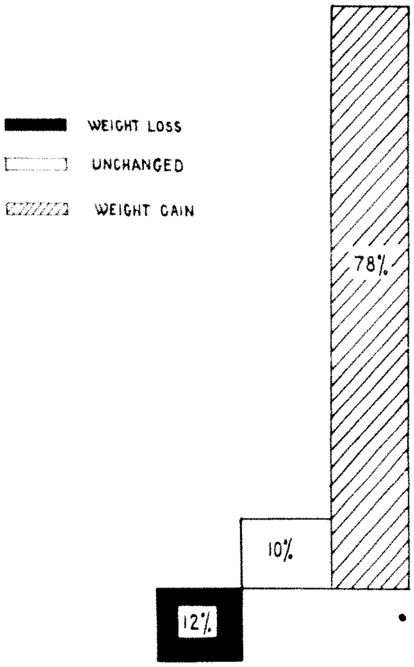

FIG. 6.—The percentage weight-gain or weight-loss in 294 patients after Polya gastrectomy for duodenal ulcer.

i. *Haemoglobin*: The range of haemoglobin level is illustrated in *Fig.* 8. Taking as normal a rang of 13·5–18 g. per 100 ml. in men and 11·6–16·5 g per 100 ml. in women, it is seen that though th haemoglobin levels in the majority of the patient fall within normal limits in both men and wome there is a substantial number of subjects in who the haemoglobin was much below the lower limit of normal.

ii. *Serum iron*: Routine screening of the levels o serum iron was carried out in all the cases even in th presence of a normal haemoglobin. The result o this investigation showed that the levels in th majority were equally distributed throughout th normal range of 60–160 μg. per ml. as illustrate in *Fig.* 9. A considerable number of patients, how ever, were below the lower limits of normal an were regarded as iron-deficient, while in som subjects the serum iron was above the norma range.

iii. *Serum vitamin B_{12}*: The levels of seru vitamin B_{12} are illustrated in *Fig.* 10. There was marked tendency for the levels to be in the lowe half of normal range with only a few of the reading being in the upper limits of normal. An appreciable number of men had readings below the lower limits of normal but no women had serum levels below 200 pg. per ml.

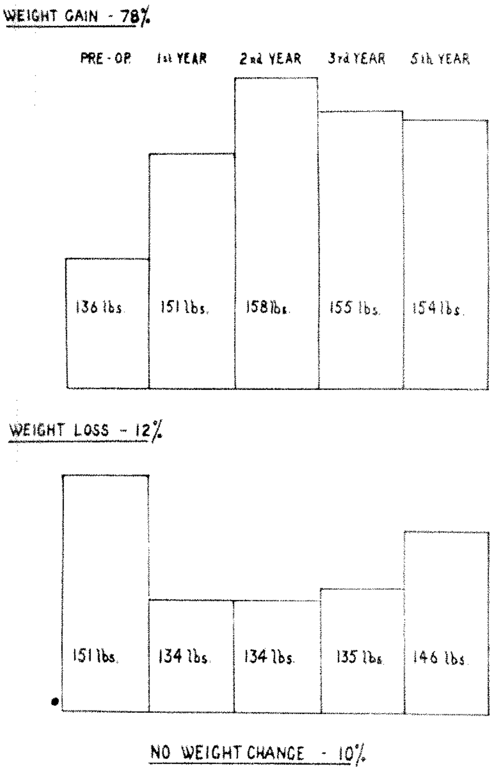

FIG. 7.—The weight changes in 294 patients during the 5-year period after Polya gastrectomy for duodenal ulcer.

iv. *Serum folic acid*: The distribution of the serum folic acid levels bore a very close resemblance to that found for vitamin B_{12}, in that the majority of patients were found to have readings at the lower limits of the normal range of 3–18 ng. per ml., as illustrated in *Fig.* 11. As in the case of vitamin B_{12} a few men but no women had levels below 3 ng. per ml.

Review of Cases found to be Anaemic.—Of the 116 cases under review, 31 cases were found to have haemoglobin levels below normal or to have reduced serum levels of iron, vitamin B_{12}, and folic acid. Investigations of these 31 patients showed that 9 had

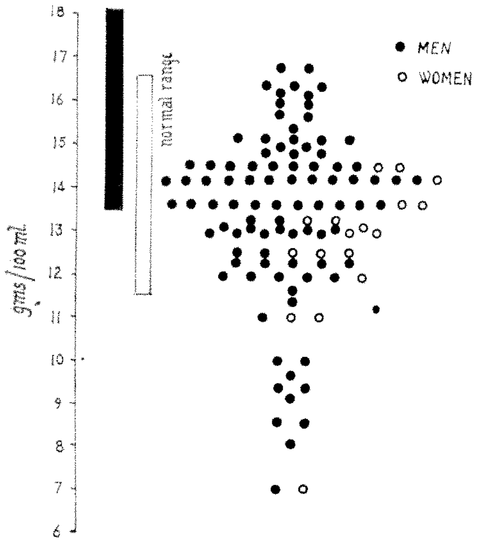

FIG. 8.—The levels of haemoglobin in 116 patients 15–20 years after Polya gastrectomy.

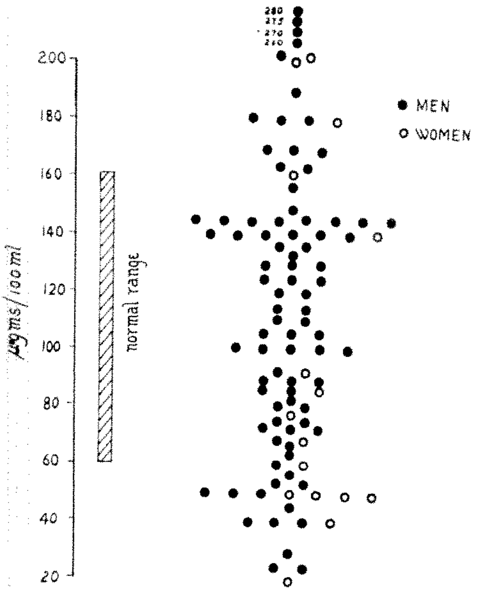

FIG. 9.—The levels of serum iron in 116 patients 15–20 years after Polya gastrectomy.

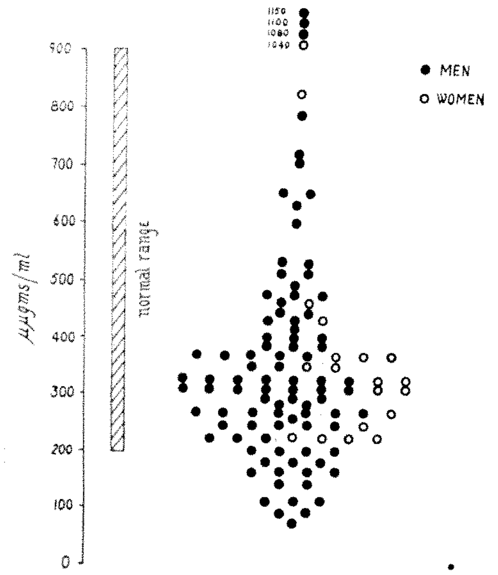

FIG. 10.—Showing the tendency for the serum vitamin B_{12} to be in the lower limits of normal, with a substantial number of subjects showing vitamin-B_{12} deficiency.

developed anaemia for some reason not in any way related to the gastrectomy. The causes of the anaemia in these 9 subjects are shown in *Table VIII*. Repeated haemorrhoidal bleeding accounted for 3 cases, while carcinoma of the colon, cirrhosis of the liver, and bronchogenic carcinoma each accounted for 1 case. One unusual discovery was the occurrence of amoebiasis of the caecum in a 50-year-old man who had had a gastrectomy 17 years previously. One woman of 55 had donated blood regularly twice a year since the time of her operation 15 years previously. The fact that there were no cases of anaemia as a result of uterine bleeding was due to the fact that in this long-term follow-up all the women patients were post-menopausal with ages ranging from 60 to 75 years.

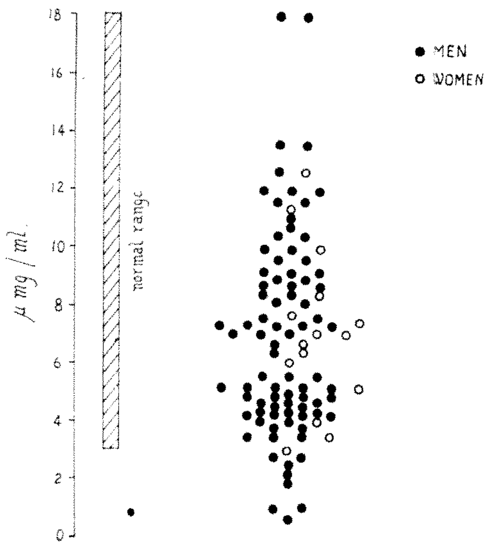

FIG. 11.—Showing that the levels of serum folic acid bear a very close resemblance to those of vitamin B_{12} 15–20 years after Polya gastrectomy.

Table VIII.—ANALYSIS OF CASES OF ANAEMIA WHICH WERE NOT RELATED TO GASTRECTOMY

Cause	*No. of Cases*
Haemorrhoids	3
Carcinoma of colon	1
Cirrhosis of liver	1
Amoeboma of caecum	1
Jejunitis	1
Bronchogenic carcinoma	1
Blood donor	1
Total	9

Of the remaining 107 cases, 22 were considered to be suffering from post-gastrectomy anaemia. Eighteen of these were men and 4 were women. These cases included anaemia due to deficiency of iron, vitamin B_{12}, and folic acid, as well as those suffering from more than one deficiency. Also included are 3 patients in whom though the haemoglobin was normal the serum iron (2 cases) and the serum vitamin B_{12} (1 case) were below the normal level. These subjects were in consequence regarded as cases of incipient iron deficiency or of macrocytic anaemia.

An analysis of the cases of post-gastrectomy anaemia is presented in *Table IX*. The overall incidence of all types of anaemia was 20·6 per cent. Men were less frequently affected (19·9 per cent) than women, of whom 23·5 per cent suffered from anaemia. Iron-deficiency anaemia was more common in women (23·5 per cent) than in men (10·0 per cent), but vitamin B_{12} deficiency (4·4 per cent) and folic acid deficiency (2·2 per cent) were found in male patients only.

The overall picture showed that iron-deficiency anaemia (12·1 per cent) was much commoner than vitamin-B_{12} and folic acid deficiency, in which the incidence of anaemia was 3·74 and 1·89 per cent respectively. Combined deficiencies of iron and vitamin B_{12} (1·87 per cent) and of folic acid and vitamin B_{12} (0·9 per cent) were also encountered in this analysis.

Response of Post-gastrectomy Anaemia to Replacement Therapy.—The response to oral iron in doses of 200 mg. of ferrous sulphate three times a day was rapid and satisfactory in those cases of iron-deficiency anaemia in which the serum vitamin B_{12} was within normal limits. Two middle-aged patients presented as cases of incipient iron deficiency with near-normal haemoglobin but with serum-iron levels of around 50 mg. per cent. The clinical improvement and sense of well-being following iron therapy were more than commensurate with the increase in the haemoglobin level. In 2 cases, however, the response to iron was disappointing. In one of these patients there was an associated low level of serum vitamin B_{12}, and though the response to oral iron and to parenteral

Table IX.—ANALYSIS OF CASES OF ANAEMIA 15–20 YEARS AFTER POLYA GASTRECTOMY FOR DUODENAL ULCER

TYPE OF DEFICIENCY	MALES		FEMALES		TOTAL	
	No. of Cases	Percentage	No. of Cases	Percentage	No. of Cases	Percentage
Iron	Actual, 7 Incipient, 2	10·0	4	23·5	13	12·10
Vitamin B_{12}	Actual, 3 Incipient, 1	4·4	—	—	4	3·74
Iron and vitamin B_{12}	2	2·2	—	—	2	1·87
Folic acid	2	2·2	—	—	2	1·87
Folic acid and vitamin B_{12}	1	1·1	—	—	1	0·90
Total	18	19·9	4	23·5	22	20·60

vitamin B_{12} was poor when given separately, when given in combination a satisfactory response was attained. In the other case who suffered from persistent post-gastrectomy symptoms and who was regarded as a 'gastric cripple' the response to Cytamen and iron was disappointing.

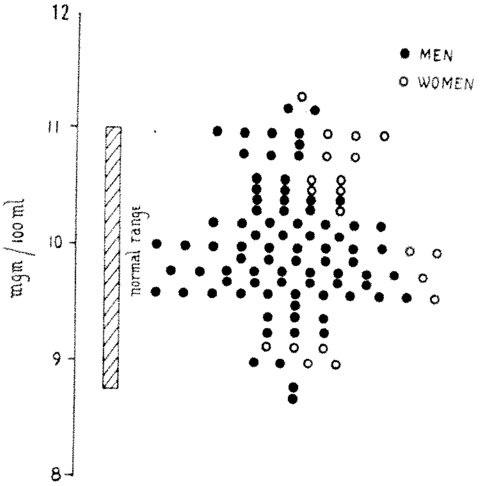

FIG. 12.—The levels of serum calcium in 102 cases 15–20 years after Polya gastrectomy.

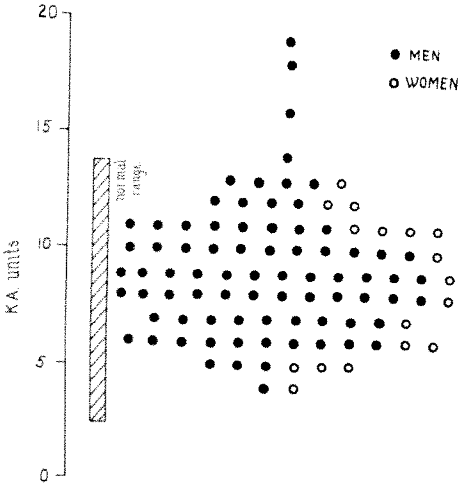

FIG. 13.—The levels of serum alkaline phosphatase 15–20 years after Polya gastrectomy. Three cases showed levels above the upper limits of normal and were subsequently investigated.

Vitamin-B_{12} deficiency was treated by the injection of 1000 μg. of Cytamen at fortnightly intervals for 2 months followed by monthly injections. In folic acid deficiency 2 mg. of folic acid were given three times a day followed by monthly injections of 1000 μg. of Cytamen. The response to therapy was satisfactory in all except 1 subject.

c. Post-gastrectomy Bone Disease.—The maintenance of normal bone structure depends on the provision of an organic osteoid matrix and adequate mineralization by the constant ionic interchange across the surface of the crystalline bone. Inadequate intake of calcium, vitamin-D deficiency, increased bowel loss of calcium as a result of steatorrhoea, post-cibal acidosis, and poor intake of protein may all affect bone structure. Since these conditions of impaired absorption are likely to be present after gastrectomy, such subjects may be more susceptible to alterations of bone structure and prone to develop either osteomalacia or osteoporosis, or a combination of both conditions. Review of the literature suggests that metabolic bone disease may occur after gastrectomy more frequently than is realized.

Because of these considerations all the long-term post-gastrectomy patients were screened specifically to discover evidence of metabolic bone disease. It was realized from a review of the literature that the parameters indicating incipient or established post-gastrectomy bone disease are ill defined, and diagnosis rests on the assessment of a combination of a number of factors—biochemical, radiological, histological, and clinical.

Biochemical examination consisted of routine estimations of the serum calcium, the serum phosphatase, and the calcium/phosphate product. The serum alkaline phosphatase was estimated in all the cases and levels above 13 K.A. units were regarded as abnormal. In certain cases the 24-hour urinary calcium excretion was estimated, though the limitations in the value of this estimate were appreciated.

Radiological screening consisted of estimation of the 'metacarpal', 'femoral', and 'vertebral biconcavity' indices as described by Nordin (1970), together with the observation of osteoporotic changes in the spine, fracture of the ribs, or the presence of Loosers zones in the long bones.

Histological tests consisted of open-bone biopsy of the iliac crest, but this procedure was confined to those cases with a strong suspicion of bone disease.

Clinical inquiry recorded the grading of the results of gastrectomy as already outlined, noting the occurrence of weight changes and examination of the haematological state. Inquiry was made regarding muscle weakness or bone pain, but the results of this inquiry in elderly arthritic patients were confusing and unhelpful. The presence or absence of steatorrhoea was especially noted.

In this review 102 cases who had had gastrectomy 15–20 years previously were screened routinely by the tests outlined above.

Serum calcium: The serum-calcium levels in 102 cases are depicted in *Fig.* 12. As will be seen the vast majority of readings fall well within the normal limits in both men and women, except for 2 patients marginally below and 3 patients marginally above the limits of normal.

Serum alkaline phosphatase: The results of the routine screening of the serum-alkaline-phosphatase levels are shown in *Fig.* 13. All the subjects were well within the normal range, except for 3 who were significantly above the upper limits of normal and who were subsequently more fully investigated.

Bone radiography: Any patient showing an abnormality in the routine radiological examinations as outlined was subjected to further biochemical and clinical study.

Of the 102 cases screened in this long-term follow-up, 13 cases were suspected of suffering from bone disease either because of biochemical or radiological abnormality. The details of these cases are presented in *Table X*. All were male patients in middle life or old age, the youngest being 36 and the eldest 77, with an average age of 64. Operation had been performed 13–19 years previously.

Cases 1, 2, 3, and 9 were selected for scrutiny because the alkaline phosphatase was well above the normal level of 13 K.A. units. *Case* 1, an elderly hypertensive man of 71, had frequent epistaxis and suffered from hypochromic anaemia and coronary disease. All other investigations including bone biopsy failed to confirm the presence of metabolic bone disease. *Case* 2, a cripple from dysentery and gassing in the First World War, had developed pulmonary tuberculosis in 1958. After a full investigation of the metabolic state post-gastrectomy bone disease could not be confirmed and he was considered to be suffering from senile osteoporosis and arteriosclerosis. *Case* 3 was found to have secondary deposits in his bones from a bronchogenic carcinoma and from which he has since died. *Case* 9 was found to be suffering from Paget's disease and suspected carcinoma of the prostate.

Table X.—THE INVESTIGATIVE DETAILS OF 13 CASES O

CASE	AGE AND SEX	GRADE	TIME INTERVAL (years)	WEIGHT	TOTAL PLASMA PROTEIN	BLOOD STATE	SERUM			DAILY URINARY Ca (mg.)

Ca, calcium; P, phosphorus.

* The special features which were discovered on routine screening and which evoked further investigation.

Case 8, an alcoholic aged 65 who suffered from hypochromic anaemia, was selected for scrutiny because of spinal osteoporosis. He was found to be suffering from Paget's disease of the pelvis and osteoporosis was confirmed on bone biopsy. *Case* 4, a man of 54, was also selected for investigation because of the presence of spinal deformity and a low urinary-calcium excretion. Further inquiry elucidated the history of spinal injury, and all other tests showed no evidence of post-gastrectomy bone disease.

Cases 5, 6, 7, 11, and 13 were all selected for scrutiny because of the radiographic appearances of the spine. Of these, *Cases* 5, 7, and 13 were considered to have osteoporotic changes consistent with their average age of 74. *Case* 6, a man of 72 who showed signs of avitaminosis and weight-loss, was considered to be a failed gastrectomy and was placed in grade III mainly because of bilious vomiting.

TOMY SUSPECTED OF SUFFERING FROM BONE DISEASE

	Bone Radiographs			Bone Biopsy	Bone Pain	Muscle Weakness	Steatorrhoea	Comment
e	Ribs	Long Bones	Metacarpal Index					
ty 0·9	Normal	0·64 Normal	0·44 Normal	Normal	Normal	None	None	Repeated epistaxis. Coronary thrombosis. No evidence of bone disease
osis	Normal	Normal	—	—	None	None	Present	Chronic dysentery since war; gas casualty in 1917. Pulmonary tuberculosis in 1958
y	—	—	—	—	—	—	—	Found to have bronchial carcinoma
y of ty normal	Normal	0·57 Normal	0·47 Normal	—	None	None	None	Old spine injury; no evidence of bone disease
osis*	Normal	0·91 Normal	0·57 Normal	—	None	None	None	Radiographs of spine considered normal for age
osis*	Normal	—	—	Normal	None	None	None	Afferent-loop syndrome. Avitaminosis
osis*	Normal	0·56 Normal	0·5 Normal	—	None	None	Occasional	—
osis*	Normal	0·51 Normal	0·39 Low	Moderate degeneration of osteoporosis	None	None	None	Heavy drinker. Paget's disease of pelvis
ry ?	Normal	—	—	—	Present	None	None	Carcinoma of prostate? Paget's disease? Renal function normal
	Normal	—	Periarticular osteoporosis in left hand	—	—	None	None	Early rheumatoid arthritis?
* ty 0·33	—	0·55 Normal	0·55 Normal	—	None	None	None	Old Scheuermann's disease
	Normal	0·56 Normal	0·38 Low	—	None	None	None	High blood-pressure. Amoebiasis
osis ?*	Normal	0·48 Normal	0·4 Normal	—	None	None	None	Pulmonary fibrosis involving all the aorta

The serum calcium and phosphorus were normal and the daily urinary output of calcium was within normal limits. Bone biopsy was also normal. This patient has now agreed to have the Polya operation converted to one of the Billroth-I type. *Case* 11, one of the younger patients in the series, was also selected for investigation because of spinal curvature and suspected bone change. Investigations suggested that he had developed kyphosis in adolescence owing to Scheuermann's disease.

Case 12 was rather unusual in that this hypertensive 53-year-old man showed a low 'metacarpal' index of 0·38 on radiographs of the hand and he also had a high serum calcium. On admission he was found to be suffering from amoebiasis affecting the caecum and terminal ileum. *Case* 10 also showed an unusual appearance on radiographs of the metacarpal bone and was thought to be an early case of rheumatoid disease. The final case, *Case* 13, showed slight osteoporotic changes of the spine but the spinal 'biconcavity' index was normal, as were the 'femoral' and 'metacarpal' indices.

In this group of 13 cases, 9 were assessed as symptom-free in grade I, 3 as satisfactory in grade II, and 1 case suffering from bilious vomiting, loss of weight, and avitaminosis as a failure in grade III. This group of cases of suspected metabolic bone disease therefore showed the same percentage of patients in each category and mirrored the grading results of the series as a whole.

After the most careful consideration of the biochemical, clinical, or radiological state none of these cases could be considered to be suffering from post-gastrectomy bone disease, and bone biopsy was normal in those considered to be most likely examples of bone dystrophy.

d. Plasma Proteins.—Though it was realized that the plasma-protein levels do not reflect the extent of nitrogen loss unless this is severe, it was considered that long-continued protein depletion might over a period of 15–20 years affect the levels of the plasma proteins. In view of this, routine estimation of the plasma-protein levels was carried out in all cases of long-term review.

The levels for total plasma protein are shown in *Fig.* 14. The levels in all patients fall well within the normal range for total plasma proteins. Estimation of the serum-globulin levels, however, produced different and surprising results, as shown in *Fig.* 15. The levels of globulin showed marked reductions in both men and women, with appropriate alterations in the albumin : globulin ratio.

Pulmonary Tuberculosis.—In 8 cases in the series there was an association between tuberculosis and partial gastrectomy. In 3 patients who had had pulmonary tuberculosis associated with a long-standing duodenal ulcer the treatment of the pulmonary lesion was inhibited by the presence of severe dyspepsia. All 3 responded satisfactorily to gastrectomy with marked improvement in their general health. Another patient who had formerly had pulmonary tuberculosis had a gastrectomy for duodenal ulcer and subsequently developed stomal ulceration. Revision gastrectomy and vagotomy were performed and at no time was there any evidence of recrudescence of the pulmonary lesion.

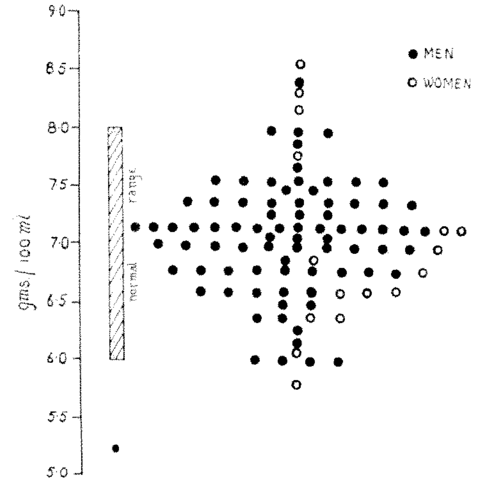

FIG. 14.—Showing that the total blood-protein levels were within normal limits in 102 cases 15–20 years after Polya gastrectomy.

Three other cases were known to have had active tuberculosis before operation and in none of these cases was the result entirely satisfactory. One of the patients had had a nephrectomy for a tuberculous kidney in 1948 and had doubtfully controlled pulmonary tuberculosis at the time of gastrectomy. Four years after gastrectomy he developed tuberculous epididymitis and recently has had a spontaneous pneumothorax. Another patient with pulmonary cavitation has made only moderate progress after gastrectomy, but this may be partly accounted for by advancing age and chronic urinary infection. The remaining case of known pulmonary tuberculosis before operation was a casualty of dysentery and gassing in the First World War. Progress after gastrectomy was only moderate and he has recently been investigated as a possible example of post-gastrectomy bone disease.

In only 1 patient has pulmonary tuberculosis developed after operation. This woman, who had a Polya gastrectomy in 1952, lost weight consistently after her operation and was found to have a pulmonary focus 9 months later. She died of a fulminant pulmonary tuberculosis in 1954, 2 years after operation.

DISCUSSION

It is not proposed in this commentary to discuss at length the details recorded in this 20-year prospective survey but merely to emphasize certain features of this series in the light of recent publications on the immediate and long-term results of various surgical procedures in the treatment of duodenal ulcer.

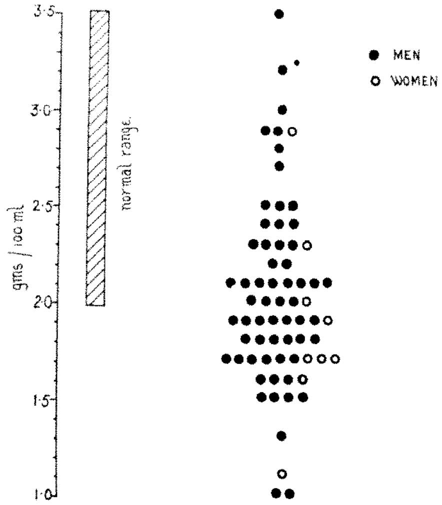

FIG. 15.—Showing that the levels of serum globulin tended to be in the lower limits of normal or to be reduced in both male and female patients 15–20 years after Polya gastrectomy.

This paper records the results of a carefully planned prospective and entirely personal study which was started in 1950 when gastrectomy was considered the treatment of choice in duodenal ulcer. In spite of the fact that the tide of surgical opinion began to ebb away from gastrectomy on account of its mortality and its long-term consequences, this prospective study has continued up to the present time when the tide of opinion has changed and has once again begun to flow in favour of gastrectomy.

The Overall Results.—Of the 800 cases of duodenal ulcer, 80 per cent were entirely symptom-free after operation. In these patients there was a degree of excellence in the results which was particularly noticeable when the ulcer was extensive and penetrating deeply into the pancreas or liver. The effect of the removal of such an ulcer was quite dramatic in producing an almost immediate improvement in the general condition and appearance of the patient. It is perhaps permissible to note that many of the registrars who took part in the follow-up examinations commented on an indefinable well-being in post-gastrectomy patients which was not present in the post-vagotomy cases which they were accustomed to see in other follow-up clinics.

The results were marginally better in men than in women in grade I, which reflects the usual experience. The failure rate of 6 per cent was, however, the same in both sexes though the cause of failure was different. A higher mortality-rate and the greater tendency to stomal ulceration were the main causes of the unsatisfactory results in men, while in women the occurrence of post-prandial symptoms accounted for 5·2 per cent of the failures.

Mortality-rate.—The risk of death from elective operation was 0·7 per cent even though there was no exclusion of elderly and poor-risk patients suffering from extensive penetrating ulcers. Most of the deaths occurred in the earliest years of the study when a hard core of very difficult cases had to be dealt with, but in the later years the mortality fell to a much lower level. The mortality-rate is comparable to those recorded by Pannett (1938; 0·86 per cent) and Hosford (1949; 0·5 per cent) in retrospective studies and to that recorded by Goligher and others (1968), who in the Leeds/York trial did not have a single death after gastrectomy in 109 cases. The 'escape clause' though not often evoked for the very difficult case must, however, be considered in assessing these excellent results.

The dangers of emergency gastrectomy are shown by the much higher mortality-rate of 22·7 per cent. The high death-rate was contributed to by a variety of factors. Many of these deaths occurred in the early part of the trial when patients with giant penetrating ulcers suffered from massive haemorrhage from erosion of the gastroduodenal or right gastric artery. Most of these patients were old and decrepit or those who had adamantly refused operation and only came for surgical help *in extremis*. Administrative and nursing attitudes required change so that adequate staff and facilities could be available during the night to cope with these desperate cases. As the result of a more enlightened outlook and the earlier reference of cases by most co-operative and helpful physician colleagues the mortality of the emergency procedure has fallen rapidly in recent years, but it would be preferable for all cases of gastroduodenal bleeding to be admitted directly to the surgical division.

The mortality-rate was entirely confined to male patients, and in the 152 women submitted to operation there were no deaths.

Stomal Ulcer.—In this series of 800 cases of Polya gastrectomy there were 16 cases of stomal ulcer, an incidence of 2·0 per cent. This recurrence rate is almost identical with that recorded in the Birmingham series by Brookes, Waterhouse, and Thorn (1960), where out of 826 cases there were 15 instances of stomal ulceration. The incidence in men in the present series (2·3 per cent) was higher than that in women (0·6 per cent), which reflects the usual experience. As shown in *Table III*, this complication occurs in the early months or years after gastrectomy. Half of the cases had symptoms within a year of operation. In this respect gastrectomy differs from gastro-enterostomy in which this complication can occur many years after operation (Davey, 1960).

The tendency to stomal ulcer was more marked in the younger age-groups, and though no age-group was immune from this complication the tendency to recurrence became less with advancing years.

Simple re-gastrectomy cured only 5 out of the 7 cases in which this operation was performed, but the addition of vagotomy to revision gastrectomy obviated further ulceration and was regarded as essential in the management of stomal ulcer. In no case of recurrent ulcer was there any evidence of hyperparathyroidism or of Zollinger-Ellison tumour, though these conditions were specifically looked for.

Of the 9 cases of post-gastrectomy bleeding not due to stomal ulcer, 3 developed symptoms after taking aspirin for a febrile illness. This appears to emphasize the general consensus of opinion that certain patients appear to be sensitive to aspirin and are prone to gastrojejunal bleeding with this drug.

Post-gastrectomy Syndrome.—Post-cibal symptoms of various kinds have come to be regarded as the *bête noire* of partial gastrectomy and it was partly because of these symptoms that the operation fell into disfavour. The results of the Leeds/York controlled trial of elective surgery in duodenal ulcer (Goligher and others, 1964, 1968) suggest that such post-prandial syndromes are not confined to partial gastrectomy but occur as frequently or even more frequently after vagotomy and gastro-enterostomy. In the present series women were affected twice as frequently (5·2 per cent) as men (2·6 per cent), as shown in *Fig.* 4. The incidence of post-gastrectomy syndromes in women presents a major hazard and is so well recognized that experienced surgeons approach the operative treatment of ulcer dyspepsia in female subjects with extreme caution.

In this study 17 out of the 25 cases of persistent post-gastrectomy syndrome were treated operatively. Two cases were improved by narrowing the gastrojejunal stoma, but the main success came from converting the Polya operation to one of Billroth type. In 2 cases, however, recurrent ulcer occurred after conversion, and it would seem that vagotomy should be added to the conversion procedure.

In the failed case after gastrectomy, revision procedures reduce the ultimate failure rate in men to 1·9 per cent, while in women 3·9 per cent of the patients remained in grade III (*Fig.* 5).

Weight Changes after Gastrectomy.—The difficulties of assessing weight changes after operation have already been mentioned. In this careful prospective study of 294 patients weight-loss was observed in 12 per cent of the subjects. This figure accords with that obtained by Kemp (1967), who found weight-loss in 18 per cent of 317 cases. Review of the literature shows that the recorded incidence of weight-loss varies widely from 9 to 75 per cent (Wallensten, 1954). The cause of this variation may be due to a variety of factors, of which the extent of gastric resection and diminished food intake are probably the most important.

The concept that partial gastrectomy aims primarily at excision of a proportion of the parietal cell mass has encouraged more radical gastrectomy in an effort to produce achlorhydria and freedom from recurrent ulceration (Bruce, Card, Marks, and Sircus, 1959). The misfortunes of this concept have been anticipated by the 'measured gastrectomy' of Visick (1945), who excised nine-tenths of the stomach, heedless of the elastic recoil of the measured greater curvature. The long-term review of these cases by Pulvertaft (1964) makes dismal reading.

The concept of removing the alkaline gastrin-secreting area (Kahlson, 1948), and especially the lesser curvature (Dean and Mason, 1964) and the pyloric mucosa (Ogilvie, 1938), encourages a less radical excision, as depicted in *Fig.* 2, as a means of reducing acid secretion. The technique of measuring the extent of the gastrectomy from the pylorus towards the fundus rather than from the oesophagus towards the pylorus leads to vastly improved nutritional results and with no material increase in the incidence of stomal ulceration.

In this series patients were encouraged to eat and drink as much as they liked and neither alcohol nor smoking was forbidden. Operation was to be regarded as a substitute for dietetic restriction. It may well be that the attitude of mind thereby engendered encouraged patients to eat more, and it was quite surprising how many patients had to institute slimming measures to restrict the progressive increase in weight, as shown in *Fig.* 6. Even those patients who showed an initial loss of weight in the first year tended to regain lost ground in subsequent years.

It seems likely that weight-loss is due to poor food intake as pointed out by Johnston, Welbourn, and Acheson (1958). A too radical excision of the stomach or a badly constructed anastomosis will cause postprandial discomfort and discourage the patient from eating, and nutritional changes will be inevitable. This confirms the dictum of Kinsella (1956) that the results of bad gastrectomies are bad.

Post-gastrectomy Anaemia.—The blood status has already been so fully considered that little further comment is necessary. The overall incidence of anaemia of all types was 20·6 per cent, a figure which is much lower than that recorded by Wastell (1968), who found that 5–6 years after Polya gastrectomy 33 per cent of patients suffered from anaemia, but corresponds more closely to the figure of 23 per cent quoted by Cox, Williams, and Tasman Jones (1963). The incidence was only slightly greater in women (23·5 per cent) than in men (19·9 per cent), but as already mentioned all the women in this series were post-menopausal.

The overall occurrence of iron-deficiency anaemia was much more common (12·1 per cent) than that due to vitamin-B_{12} deficiency (3·74 per cent). Women seemed to be much more prone to microcytic anaemia (23·5 per cent) than men (10·0 per cent). Anaemia due to vitamin-B_{12} and folic acid deficiency, however, was the prerogative of men with incidences of 4·4 and 2·2 per cent respectively. No woman in this series suffered from macrocytic anaemia. The overall incidence of macrocytic anaemia was somewhat higher than the 2 per cent recorded by Cox and others (1963), but the follow-up in the present series covered the period of 15–20 years after gastrectomy.

The response to appropriate iron or vitamin-B_{12} therapy or to a combination of both when multiple deficiencies were present was highly satisfactory. This emphasizes the fact that these supplements should be given prophylactically unless a constant review of every case is carried out.

Post-gastrectomy Bone Disease.—The screening of all long-term cases with a view to uncovering any case of post-gastrectomy bone disease has already been fully described. In none of the 13 suspects (*Table X*) admitted for extensive scrutiny could the diagnosis be established. It is of importance to note that 6 of the patients were over 70 and all except 1 were above the age of 53, so that the radiological bone changes might well be those associated with advancing years (Newton-John and Morgan, 1968). It may well be that a similar review of patients in the same age and sex grouping would reveal a similar state of the bone metabolism, and that the incidence of post-gastrectomy bone disease has been overstressed (Slaney, 1971).

Plasma Proteins.—Though it was not expected that the total plasma-protein levels would be materially altered in the absence of gross malnutrition the marked reduction in the globulin levels was an accidental finding for which at present no explanation can be offered.

COMPARISON OF PARTIAL GASTRECTOMY WITH VAGOTOMY AND DRAINAGE FOR DUODENAL ULCER

In drawing comparisons between the results of these two procedures difficulties are encountered for a variety of reasons. Prospective studies are rare and the criteria of case selection so frequently ill defined that comparisons may be attempted between groups of patients in whom the natural history of their ulcers may be quite different. The type and extent of the duodenal ulcer are virtually unimportant in gastrectomy where the ulcer is removed, except in that it presents a technical operative problem. In vagotomy and drainage, however, the extent and type of the ulcer are of considerable importance, not only in determining the type of drainage procedure but also for other reasons. The results obtained from vagotomy in a case of a large duodenal ulcer penetrating deeply into the pancreas or liver may be very different from those obtained in a case where the duodenum is scarred and only somewhat deformed, and yet the condition of the duodenum remains undescribed in the recorded series of the results of vagotomy and drainage.

The variants of vagotomy produce further difficulties in making comparisons, in that the effects of truncal as opposed to selective vagotomy are not yet accurately assessed and the incidence of incomplete vagotomy is not always recorded. The different drainage procedures, such as gastro-enterostomy, the various types of pyloroplasty, and even anterior pylorectomy (Holt and Lythgoe, 1965) add still further to the confusion and uncertainty.

The present popularity of vagotomy and drainage is due to the low mortality, the ease of performance, the supposed freedom from side-effects, the preservation of the gastric reservoir, and the better nutritional state of the patient. Though the first of these claims is generally accepted, the latter features are somewhat in doubt.

Mortality.—It must be admitted that the generally accepted mortality figure for partial gastrectomy for duodenal ulcer is 2–3 per cent though much higher rates are recorded in special gastro-intestinal units (Small, Cay, Dugard, Fircus, Falconer, Smith, McManus, and Bruce, 1969; 4·4 per cent). The death-rate in the present series of 0·7 per cent for gastrectomy corresponds to that recorded for vagotomy by Hoerr (1953; 0·5 per cent) and Crile (1952; 0·4 per cent). The very lowest mortality figures after vagotomy have, however, been recorded by Feggetter and Pringle (1963), where out of 1600 cases there were only 6 deaths, a mortality-rate of 0·37 per cent.

The surgical opinion of recent years has been so much in favour of vagotomy and drainage that a new generation of surgeons has grown up with limited experience in gastrectomy for peptic ulcer. A major return to gastrectomy as the operation of choice would undoubtedly lead to a temporary increase in the mortality-rate.

Recurrent Ulcer.—The apparent ease of vagotomy is illusory in that the Hollander (1948) insulin test shows that in 10–40 per cent of cases nerve section is incomplete and, as might be expected, success is related to the experience of the surgeon (Ross and Kay, 1964). Recurrence of ulceration after incomplete vagotomy is prohibitively high, but even in experienced hands the generally accepted figure of 5 per cent compares unfavourably with the 2 per cent recurrence rate recorded in this and many other series after gastrectomy. Late recurrence after gastrectomy is exceptional but may still take place 10 years after vagotomy, as noted by Feggetter and Pringle (1963).

Post-gastrectomy Syndromes.—The preservation of the gastric reservoir may lead to the impression that post-cibal symptoms are much less likely to occur after vagotomy than after gastrectomy. This reputation has, however, become somewhat tarnished recently. The findings of Cox (1968) and the results of the comparative series in the Leeds/York trial (Goligher and others, 1964, 1968) indicate that side-effects are marginally more common after vagotomy and gastro-enterostomy than after partial gastrectomy.

Oesophageal Lesions.—The rare occurrence of oesophageal stenosis after Polya gastrectomy for duodenal ulcer, as described here and elsewhere (McKeown, 1958), has its counterpart in the occasional dysphagia and oesophageal reflux which occurs after vagotomy, as recorded by Williams and Woodward (1967) and Tanner (1951), who recorded an incidence of 'cardiospasm' or 'achalasia' in 3 per cent of cases.

Diarrhoea.—Just as the dumping syndrome has been regarded as the *bête noire* of partial gastrectomy, diarrhoea is now regarded as the curse of vagotomy. Though much controversy rages over the incidence of this complication, in a series of 209 cases followed up for 10–14 years by Feggetter and Pringle (1963) 29 per cent of the patients had diarrhoea, which proved troublesome in 9 per cent of cases. In certain cases more easy bowel action was regarded as beneficial (Feggetter, 1970).

The Nutritional State.—It is in regard to the nutritional state both immediately after operation and in the long term that advantages are so specially claimed for vagotomy and drainage. Preservation of the gastric reservoir does not prevent weight-loss, as emphasized by Wheldon, Venables, and Johnston (1970), while the figure of weight-loss in 11 per cent of vagotomy cases recorded by Burge and Pick (1958) corresponds closely to the 12 per cent of patients who lost weight in this series.

Anaemia.—The onset of anaemia bears a definite relationship to the time interval after operation, with a tendency for microcytic anaemia to appear 3–5 years after operation and macrocytic anaemia to occur at a much later date. By good fortune a recent review of the long-term results of vagotomy in the Feggetter (1970) series by Wheldon and others (1970) provides an excellent opportunity for comparison of the incidence and types of anaemia occurring 15–20 years after operation. In the present series the incidence of all types of anaemia was 20·6 per cent, compared with 43·5 per cent in patients 15 years after vagotomy and gastro-enterostomy. The fact that Wastell (1968) noted a lower incidence after pyloroplasty suggests that the type of drainage procedure might be significant. After vagotomy and gastro-enterostomy anaemia was of the iron-deficiency type and in only a few was the anaemia of the vitamin-B_{12}-deficiency type. In post-gastrectomy patients, as has already been outlined, about one-quarter of the cases of anaemia were due to vitamin-B_{12} (and folic acid) deficiency.

Bone Disease.—Neither in the present series nor in the very comparable post-vagotomy series (Wheldon and others, 1970) of long-term follow-up has there been a single case of bone dystrophy.

From these considerations it would appear that the pendulum of surgical opinion which had swung away from partial gastrectomy to vagotomy with drainage is more equally poised at the present time. Now that it is more fully realized that the preservation of the gastric reservoir in vagotomy does not lead to less post-prandial symptoms, adjudication between the two procedures must rest on other considerations.

The low mortality and higher recurrence rate after vagotomy must be set against the higher mortality but lower recurrence rate after partial gastrectomy. In this assessment the mortality-rate is of paramount importance. If the facilities and skills of the unit are able to reduce the mortality of partial gastrectomy to under 1 per cent, then gastrectomy is preferable, in that the recurrence rate is lower, diarrhoea is not a complication, and the post-prandial discomforts are no worse than those after vagotomy and drainage. In addition, the effect of removing a deep penetrating ulcer is quite dramatic in improving the appearance and well-being of the patient to a degree not obtainable by vagotomy and drainage. The nutritional state of a successful gastrectomy is similar to that after vagotomy, and in the long term the incidence of anaemia appears to be somewhat less.

Vagotomy and drainage, however, provides a most effective surgical treatment and in average hands carries a low mortality. The higher recurrence rate can be dealt with by further surgery, and recurrent ulcer is by no means the worst complication of the surgery of peptic ulcer.

The choice of operation will therefore depend more on the local facilities available and on the experience of the individual surgeon rather than on the intrinsic merits of either procedure.

Acknowledgements.—I wish to thank the medical practitioners of Northallerton, Darlington, and the surrounding country areas who have co-operated so enthusiastically in obtaining details regarding the patients and for their help at all times. I should also like to thank my consultant colleagues, the late Dr. G. D. Owen, Dr. A. W. B. Edmunds, and Dr. J Hampson, for their help and co-operation at all times.

I am most grateful to my anaesthetic colleagues, especially to Dr. K. H. Oldfield, Dr. J. G. Cranmer, Dr. A. P. Wright, Sir Edward Holden, Bart., and Dr. H. C. Butterworth, and to the resident medical and nursing staff for their expert care of the patients.

All the radiographs in the long-term follow-up were examined by Dr. Aideen Irwin, Consultant Radiologist, who worked out the various indices. To her and to Dr. Donald P. Degenhardt, who kindly reviewed the cases of suspected bone dystrophy, I would like to express my sincere appreciation.

My special thanks are due to Professor Geoffrey Slaney for reading the draft of this paper and for many most helpful suggestions, which I acknowledge with gratitude.

I would also like to thank Mr. William Pearson for the great care that he has taken in making the illustrations, and Dr. P. M. Colman, Dr. J. Tregillus, and Dr. D. E. Lamb for their help with pathological specimens.

The biochemical assays and estimations of serum iron, vitamin B_{12}, and folic acid have been carried out by Dr. R. E. Potts of the Central Clinical Laboratory, General Hospital, Middlesbrough, whom I wish to thank especially.

The organization of the gastric follow-up clinics and the keeping of the extensive gastric *pro formas* has been in the most capable hands of Mrs. Eileen Raine without whose help this work could not have been completed and to whom my special thanks are extended.

A TECHNIQUE FOR CREATING A SKIN-LINED HEMITHORAX

BY LADE WOSORNU*

ROYAL POSTGRADUATE MEDICAL SCHOOL, HAMMERSMITH HOSPITAL, LONDON

SUMMARY

Prosthetic lungs could permanently occupy the pleural space which must first be lined with silicone 'skin', i.e., Dacron-backed silicone membrane (Peirce, 1966). Initial experiments in dogs showed that the pleural membrane would not readily accept silicone 'skin'; rather, the solution lay in the use of autogenous skin-grafts. A readily reproducible technique has been developed for transforming the left hemithorax of SPF rats into stable skin-lined cavities which can be opened to atmospheric pressure without embarrassing breathing in the contralateral lung.

Autogenous skin was formed into 35 × 20-mm. sacs and grafted into the left pleural spaces of 150 male SPF rats of mean weight 240 ± 30 g. One hundred and thirty-two (88 per cent) survived 4 weeks or more. In these the skin-lined cavity grew to occup the hemithorax, displacing the left lung. In 75 rat the cavity was opened to the exterior and sutured t the skin, thereby creating a permanent 5–8-mm opening directly through the chest wall. Fifty-nine c the 75 rats so exposed survived.

The mean pressure in the cavity was $+2{\cdot}9 \pm 0{\cdot}6$ cm H_2O before it was opened to the exterior; after th creation of the stoma the mean pressure in the cavit became $-2{\cdot}5 \pm 0{\cdot}6$ cm. H_2O ($P < 0{\cdot}001$), and the nev pressure was in phase with and was similar in mag nitude to the oesophageal pressure. The skin-line hemithorax is presented as the model of a cavity whic could be employed to house prosthetic organs de signed for permanent implantation inside the ches cavity.

IT has been shown in short-lived experiments that i is feasible to implant prosthetic lungs (Bodell, Head

---

* Present address: Ghana Medical School, P.O. Box 4236, Accra, Ghana.

Head, and Formolo, 1965). Taking the concept further, Peirce (1966) described a prosthetic lung which permanently occupied the pleural space which must first be lined with silicone ‘skin’ (i.e., Dacron-backed silicone rubber membrane); if this was achieved the pleural cavity would have been exteriorized effectively. Peirce assumed that the pleural membrane would readily accept silicone ‘skin’, an assumption which others have questioned (Melrose, 970).

Initial experiments showed that in dogs silicone skin’ provoked much pleural effusion which needed protracted chest drainage; 1 dog developed empyema (Wosornu, 1971). A different lining for the pleural pace was sought in the use of autogenous skin-grafts, and experiments in 9 other dogs showed that free skin-grafts would ‘take’ on the normal pleural surfaces (Wosornu, 1972).

The aims of the observations recorded here were twofold. First, to attempt to transform the hemithorax into a skin-lined cavity. Secondly, to investigate the possibility that the skin-lined hemithorax could be opened to the exterior without embarrassing breathing in the contralateral lung (*Fig.* 1). The work was undertaken because the skin-lined hemithorax could be employed to house prosthetic organs designed for permanent implantation inside the chest cavity.

The first consideration, however, was the choice of a suitable experimental animal in which the two objecives could be pursued and Specific Pathogen Free SPF) rats were chosen. The experimental model was obtained in two stages: in stage 1 autogenous skin was grafted into the normal pleural space and in tage 2 the skin-lined hemithorax was opened to the exterior.

MATERIALS AND METHODS

Male albino Wistar rats of mean initial weight 240 ± 30 g. (purchased from Carworth, Huntingdon, England) were used. They were kept under standard laboratory conditions and all the operations were performed under general anaesthesia. A glass jar containing methoxyflurane (Penthrane) was connected to an open Perspex box which measured 20 cm.^{3} When oxygen was bubbled at the rate of 1–2 litres a minute hrough the methoxyflurane and the box was closed the concentration of methoxyflurane was sufficient to anaesthetize a 240-g. rat in 5–8 minutes.

An elliptical piece of full-thickness skin was excised as a free graft from the shaved back of the rat and the defect was closed without tension. The skin was pinned down and defatted in the usual way with a scalpel. It was then folded on itself and a 35 × 20-mm. rectangular piece was cut out. The free edges were sutured together with 00 silk, after which the specimen was turned inside out so that the hair-bearing surfaces faced inside and were thus isolated. A piece of soft silicone capillary tube (70 mm. long and 0·6 mm. external diameter) was inserted into the capsule to splint it and to give it a roughly rectangular shape (*Fig.* 2).

The rat, anaesthetized but not intubated, was placed on its right side. Through an incision 15–20 mm. long in the seventh or eighth intercostal space the capsule of skin was implanted inside the normal pleural space. The first pericostal suture was placed in the middle of the incision and tied to control the open pneumothorax. (It usually took under 90 seconds to open the parietal pleura, implant the skin capsule, and tie the first pericostal suture.) The chest was then closed in layers without drainage (*Fig.* 3).

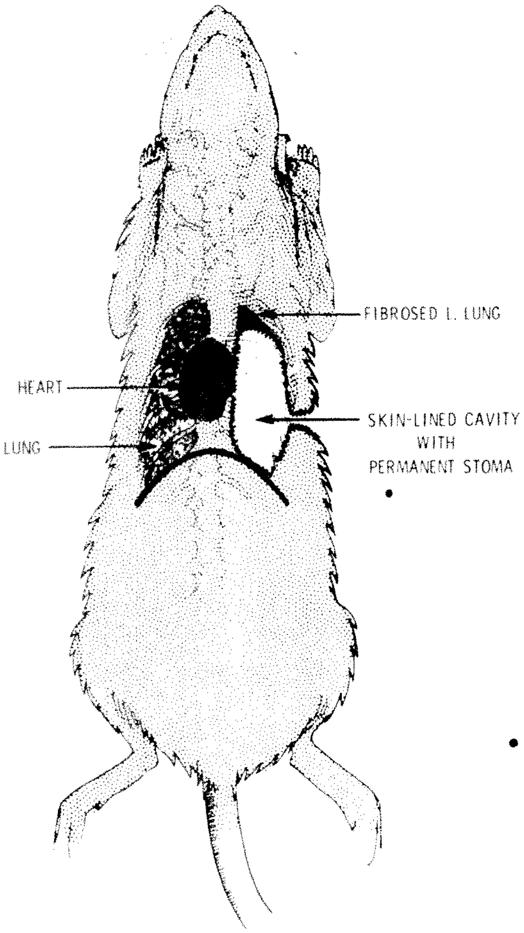

FIG. 1.—Experimental model of a cavity which could house prosthetic organs designed for permanent implantation in the chest.

Observations on the Closed Skin-lined Hemithorax.—The 150 rats which had the operation of intrapleural skin-grafting were divided into three overlapping groups and studied as follows. In group 1 (30 rats) serial chest radiographs were taken once a week for 4 weeks. The rats were anaesthetized and 1 ml. of 45 per cent Hypaque was injected into the skin-lined pleural cavity under radiographic control. The transverse diameter of the cavity was measured from the radiographs, corrected for magnification, and plotted against time. The 30 rats (and 10 unoperated rats) were weighed once a week for 4 weeks; the test rats were then killed and sectioned transversely.

At the end of the fourth week the pressure inside the skin-lined hemithorax was measured in 15 other rats (group 2). A strain-gauge manometer and recorder (Emma: S. E. Laboratories, Type SE 4912 and

Type SE 3006) were employed. A rigid nylon catheter, 40 cm. long and 1 mm. internal diameter, was connected to the transducer head. The free end of the catheter was connected to a hypodermic needle (18 gauge) and both were filled with water. The needle was then introduced into the skin-lined cavity in the region of the inferior angle of the scapula with the anaesthetized rats prone. Oesophageal and normal pleural pressures were also measured. To measure oesophageal pressure the open end of the water-filled nylon catheter without the needle was used. The 15 rats and 7 others were kept for up to 8 months to ascertain their natural fate.

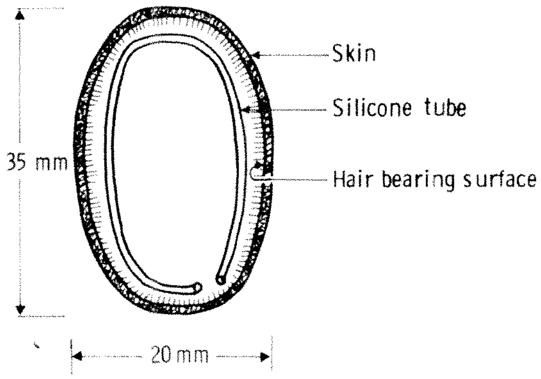

FIG. 2.—Diagram of the skin capsule for grafting into the pleural cavity of rats.

In group 3 the skin-lined hemithorax was opened to the exterior and sutured to skin, thereby creating a permanent stoma directly through the chest wall.

Table I.—COMPARISON BETWEEN WEIGHT GAINED WEEKLY BY UNOPERATED RATS WITH THAT OF THE TEST RATS

WEEK No.	WEEKLY WEIGHT-GAIN (g.)		STATISTICAL ANALYSES (d.f. = 38)	
	Test Rats ($n = 30$)	Unoperated Rats ($n = 10$)	t	P
1	1·7 ± 3·8	22·5 ± 2·4	3·08	0·004*
2	19·2 ± 2·5	31·0 ± 2·2	2·62	0·012*
3	18·5 ± 2·9	19·5 ± 2·2	0·194	0·847†
4	9·8 ± 5·1	14·5 ± 1·2	0·528	0·601†

* Significant. † Not significant.

Values in the table are given as the mean ± S.E.

Each rat was anaesthetized as before but supplementary anaesthetic was provided by keeping the face of the rats at the mouth of a beaker containing absorbent cotton-wool soaked in methoxyflurane. With the rat supine a disk of skin (about 10 mm. in diameter) was excised from a point centred 20 mm. above and lateral to the xiphoid process. The skin-reinforced parietal pleura was exposed, a disk of about 5 mm. in diameter was excised, and fluid under pressure was allowed to escape. The edges of the skin lining the hemithorax were sutured to the skin covering the chest wall to establish a skin-to-skin stoma. The operation was performed on 75 rats and consisted of 65 rats 4 weeks after the creation of a skin-lined hemithorax and 10 (out of the 15 from group 2) at week 16. (It was necessary to interrupt the operation from time to time and to change the position of the rats because they could not tolerate the supine position throughout the procedure.)

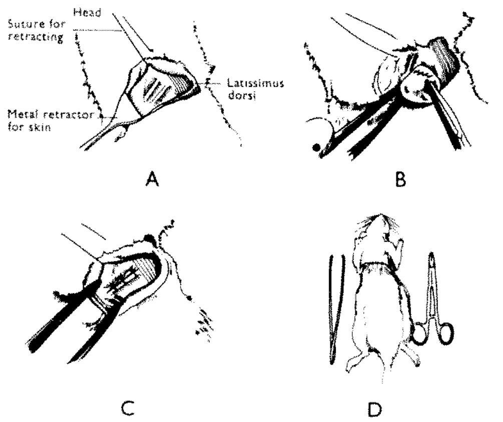

FIG. 3.—The thoracotomy and intrapleural skin-grafting in rats. A, The intercostal space is exposed. B, Implanting the skin capsule into the pleural space. C, Closure; the pericostal sutures in place. D, Closure; the final appearance with no chest drain.

Table II.—COMPARISON OF NORMAL PLEURAL PRESSURE WITH THE PRESSURE IN THE SKIN-LINED HEMITHORAX AFTER CREATION OF THE THORACOSTOMY IN RATS

	PRESSURE (cm. H_2O)		
	End of Expiration	End of Inspiration	Mean Pressure
Normal pleura ($n = 10$)	−3·4 ± 0·2	−8·7 ± 0·5	−3·7 ± 0·2
Skin-lined hemithorax ($n = 15$)	1·7 ± 0·6	−7·7 ± 1·1	−2·5 ± 0·6

* Significant. † Not significant.

Values in the table are given as the mean ± S.E.

Observations on the Open Skin-lined Hemithorax.—After the creation of the stoma the rats were screened radiologically and chest radiographs were taken. The pressure in the open cavity was measured. A piece of nylon tube (3 cm. long, internal diameter 3·5 mm.) was wedged firmly into the stoma and connected to the strain-gauge manometer; oesophageal pressure was measured simultaneously. The arterial pH, Po_2, and Pco_2, the volume of the skin-lined hemithorax, and its minute ventilation were measured (Wosornu and Melrose, 1971).

RESULTS

1. **General Progress.**—Out of 168 rats, 150 had successful intrapleural skin-grafting and 132 of these survived the next 4 weeks or longer. The grafted skin-capsule enlarged to occupy the left hemithorax as fluid accumulated in it (*Fig.* 4). Beyond the fourth week the preparation became stable.

At the end of the first 2 weeks the unoperated rats gained significantly more weight than the test rats. However, by the end of the third week the difference was lost as the test rats also thrived (*Table I*). A radiographic demonstration of the cavity before and after creation of the stoma is shown in *Fig*. 5.

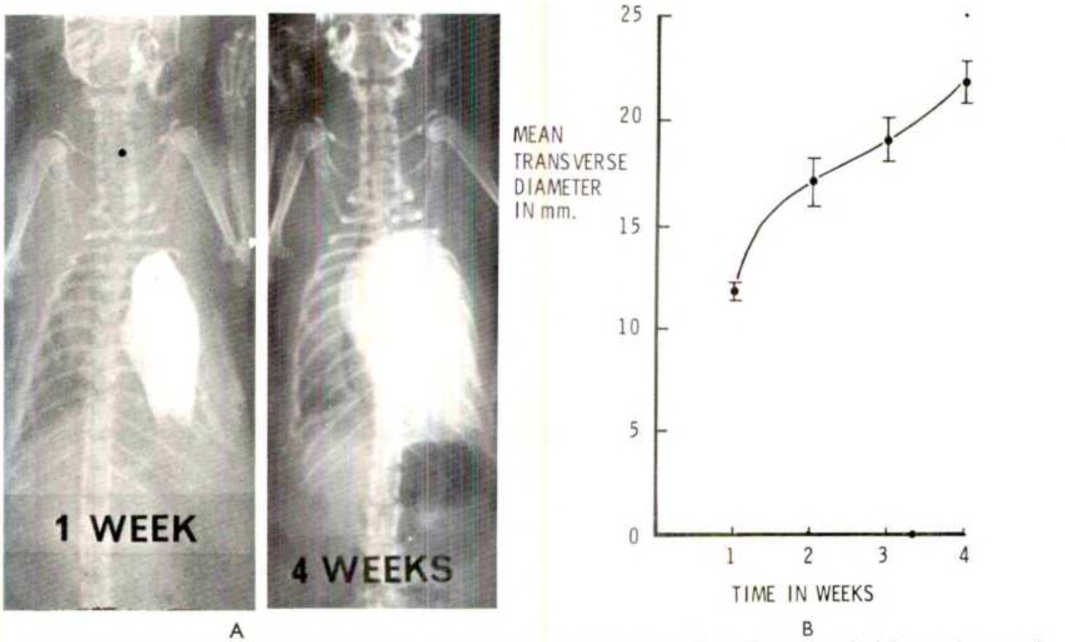

FIG. 4.—A, Radiographs of a rat with the left hemithorax outlined with 1 ml. of Hypaque. The radiograph on the left was taken 1 week after intrapleural skin-grafting; the one on the right was taken 3 weeks later. B, The transverse diameter of the cavity was measured from a series of radiographs, corrected for magnification, and plotted against time.

2. Pleural Pressure before and after Creation of the Stoma.—The mean pressure was $+2.9 \pm 0.6$ cm. H_2O in the closed skin-lined hemithorax (*Fig*. 6 A). However, after the creation of the stoma the mean pressure became -2.5 ± 0.6 cm. H_2O ($P < 0.001$). During respiration the pressure in the open skin-lined hemithorax was in phase with the oesophageal (pleural) pressure and similar to it in magnitude (*Fig*. 6 B; *Table II*).

DISCUSSION

SPF rats were chosen for the present study for three reasons. First, rats have much loose skin relative to their body weight so that if needed sufficient free skin-graft would be available. Secondly, rats need little supervision and a large series could be built up rapidly. Thirdly, SPF rats had to be used because it is generally known that non-SPF rats suffer from endemic chronic lung disease which renders them unsuitable for experiments on the respiratory system (King and Bell, 1966; Binns, Clark, and Healey, 1971).

Reports are conflicting on a simple and safe method of anaesthesia for rats intended to recover after chest surgery (Griffith and Farris, 1942; Kluge and Tveten, 1968). In the present study each rat was anaesthetized but not intubated, the chest was opened, the skin capsule was implanted into the pleural space, and the chest was closed again. It was thought that if the chest was opened for only a short time and the investigator was quick in operation the rats would survive the thoracotomy. With this approach 150 out of 168 rats (89·3 per cent) survived.

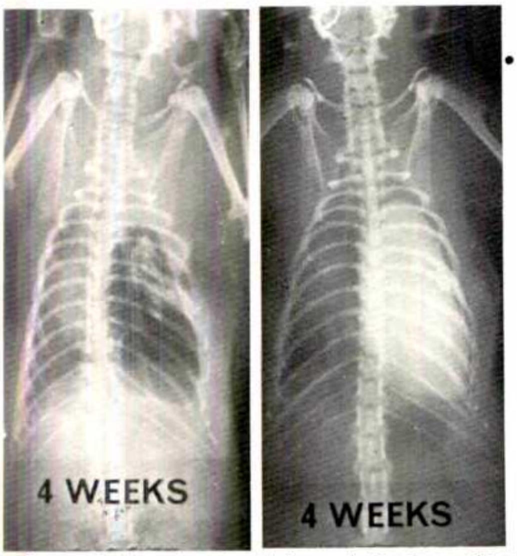

FIG. 5.—Radiographs of a rat before and after the creation of the chest stoma. The radiograph on the right shows the closed skin-lined hemithorax outlined with 1 ml. of Hypaque; the one on the left is the same cavity opened to the exterior—an artificially produced gas cavity.

The rationale behind the technique employed to create the skin-lined hemithorax was as follows. Closed capsules of autogenous skin were grafted into the normal left pleural space of 150 SPF rats of which

132 (88 per cent) survived the next 4 weeks or longer. The grafts 'took' on the surrounding structures and the skin capsules expanded as fluid accumulated in them until by the end of the second week the grafts occupied the left hemithorax, displacing the ipsilateral lung (*Fig.* 4). The cavity kept pace with the rat's growth.

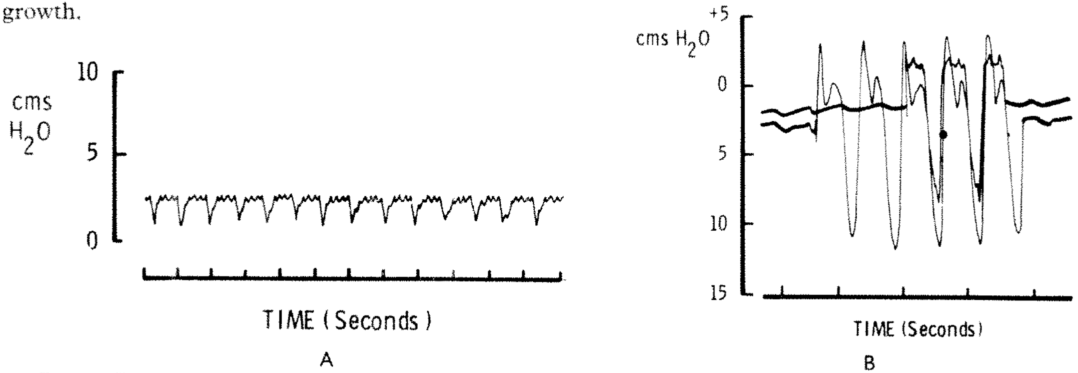

FIG. 6.—Tracings of the pressure from the skin-lined hemithorax before and after the creation of the chest stoma in rats. A, With the cavity closed the pressure was above atmospheric; the characteristic pause at the end of expiration in the rat is shown and during these pauses cardiogenic oscillations were recorded. B, After the creation of the stoma the pressure (top trace) in the cavity was subatmospheric. When oesophageal pressure (bottom trace) was recorded simultaneously the two pressures were in phase and similar in magnitude.

The mean pressure in the closed skin-lined hemithorax was $+2{\cdot}9 \pm 0{\cdot}6$ cm. H_2O, which was significantly higher than the normal mean rat pleural pressure of $-3{\cdot}4 \pm 0{\cdot}4$ cm. H_2O ($P < 0{\cdot}001$). In 59 of 75 rats (78·7 per cent) the skin-lined hemithorax was opened successfully to the exterior and a permanent skin-to-skin thoracostomy was established. Since over 78 per cent of the rats so exposed survived it was concluded that the procedure was compatible with life in most SPF rats. After creation of the stoma the mean pressure in the skin-lined hemithorax was $-2{\cdot}5 \pm 0{\cdot}6$ cm. H_2O, and during respiration the pressure was in phase with the oesophageal (pleural) pressure and similar to it in magnitude (*Fig.* 6; *Table II*).

The experimental preparation (*Fig.* 1) differs in two ways from the one suggested by Peirce (1966). First, the pleural space was lined with autogenous skin and not with silicone 'skin'. Secondly, the skin-lined and exteriorized pleural cavity could receive air from a separate opening directly through the chest wall and not from the trachea.

CONCLUSION

Three conclusions are drawn. First, a readily reproducible technique has been developed for transforming the left hemithorax of SPF rats into stable skin-lined cavities. Secondly, the cavities could be opened to the exterior without embarrassing respiration in the contralateral lung. Thirdly, the skin-lined hemithorax appeared to function as an open ventilated gas cavity. The experimental preparation was put forward as a model of a cavity which could be employed to house prosthetic organs designed for permanent implantation inside the chest. A series of experiments are in progress to see whether these conclusions are valid for larger animals also.

a word of comfort after surgery

UBRETID®

distigmine bromide

maintains smooth muscle tone
prevents urinary retention or intestinal atony

UBRETID inhibits cholinesterase for a full 24 hours, giving prolonged improvement in smooth muscle tone. Thus, with minimum inconvenience to staff or patient, a normal pattern of micturition and defaecation can usually be re-established without the discomforts of catheters or enemata. Where indwelling catheters are unavoidable, UBRETID will maintain bladder tone, reduce residual urine volume and encourage normal bladder function when the catheter is withdrawn.
Full details of UBRETID ampoules and tablets are available upon request.

AN ASSESSMENT OF ABOVE- AND THROUGH-KNEE AMPUTATIONS

By P. W. B. GREEN, B. S. HAWKINS, W. T. IRVINE, AND C. W. JAMIESON
SURGICAL UNIT, ST. MARY'S HOSPITAL, LONDON

SUMMARY

Above- and through-knee amputations have been performed in 126 patients at St. Mary's Hospital between 1961 and 1970.

Whilst there was a higher operative mortality amongst the above-knee amputees, the local complication rate was much higher in the through-knee group. The mortality rate in the two groups following discharge from hospital was high. The through-knee amputation provides a better functional result than the above-knee type but mobility in both groups might be improved by 'refresher courses' in walking training.

OVER the 10-year period from January, 1961, to December, 1970, both above- and through-knee amputations were performed by the Surgical Unit at St. Mary's Hospital. These operations were performed in consultation with the Limb Fitting Centre at Roehampton which had requested that through-knee amputations be performed on suitable patients, as it had been claimed that the procedure offered advantages over the above-knee amputation in morbidity and ease of rehabilitation. At the same time it was decided that a myoplastic technique should be used in above-knee amputations.

Table I.—NUMBER OF AMPUTATIONS PERFORMED AND THE SEX DISTRIBUTION

	TYPE OF AMPUTATION	
	Above-knee	Through-knee
No. of patients		
Unilateral	67	40
Bilateral	17	2
Total	84	42
Sex		
Male	87	38
Female	14	6
Total	101	44

All the patients in this series suffered from peripheral ischaemia. Eighty-four patients had above-knee amputations and 42 had through-knee amputations. The distribution of these patients as regards sex and whether amputation was unilateral or bilateral is shown in *Table I*. The age incidence (*Fig.* 1) of the amputees was very much the same in the two groups, except that there was a small group of young above-knee amputees who were victims of vascular trauma.

The patients with peripheral vascular disease, which was chiefly atheromatous, presented with either rest pain or gangrene. A few presented acutely with embolic phenomena. A significant number of the above-knee amputees had failed through- or below-knee amputations. The distribution of the presenting symptoms and signs is shown in *Table II*. On examination 82 per cent of the through-knee amputees had a palpable femoral pulse as opposed to 69 per cent of above-knee amputees.

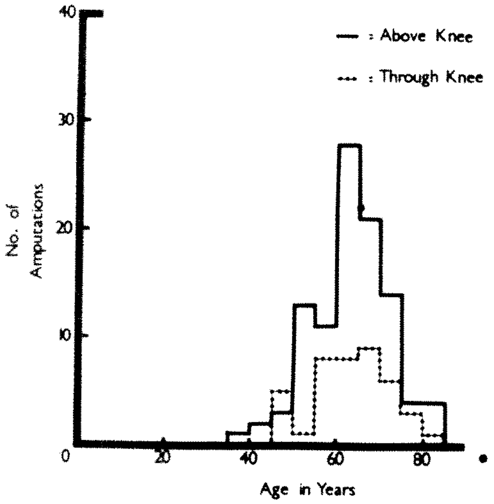

FIG. 1.—The age distribution of the amputees.

Table II.—PERCENTAGE DISTRIBUTION OF THE PRESENTING SYMPTOMS AND SIGNS

REASON FOR PRESENTATION	TYPE OF AMPUTATION	
	Above-knee	Through-knee
Peripheral vascular disease		
Rest pain	54	77
Gangrene	33	14
Embolus	3	9
Failed amputation		
Through-knee	7	—
Below-knee	3	—

Coexistent diseases have been divided into manifestations of generalized atheroma and other systemic diseases. The overall incidence of other vascular disease and the three most common individual manifestations of vascular disease are indicated together with the frequency of systemic diseases in *Table III*. The incidence of smoking in the amputees has also been included because it has an important relationship to atheromatous vascular disease, as shown by Larson, Haag, and Silvette (1961). About three-quarters of the patients in both groups were smokers, either at the time of the amputation or within the previous 10 years. Approximately half of the patients in both groups of amputees had been subjected to reconstructive surgery relating to the amputated limb before amputation was carried out, and this was evenly divided between disobliteration and by-pass in the two groups.

OPERATIVE TECHNIQUE

In the through-knee amputation the patella was preserved, the patella tendon being sutured to the cruciate ligaments, as proposed by Batch, Spittler, and McFaddin (1954). A slightly longer anterior than posterior flap was cut so that the resultant scar lay posteriorly. The wound was drained and firmly bandaged at the end of the operation. In the above-knee amputation the technique described by Dederich (1963) was used, flaps of equal length being made. The quadriceps femoris and the hamstring muscles were sutured over the end of the femur; again the wound was drained and firmly bandaged.

Table III.—PERCENTAGE INCIDENCE OF RELATED VASCULAR DISEASE AND OTHER SIGNIFICANT FACTORS

DISEASE	TYPE OF AMPUTATION	
	Above-knee	Through-knee
Vascular	43	55
Myocardial infarct	9	27
Angina	8	2
Cerebral ischaemia	8	7
Systemic		
Hypertension	28	27
Diabetes	10	12
Smoking	84	73

Table IV.—PERCENTAGE INCIDENCE OF POSTOPERATIVE MORTALITY AND MORBIDITY

	TYPE OF AMPUTATION	
	Above-knee	Through-knee
Mortality		
Unilateral amputation	13	5
Bilateral amputation	41	—
Delayed healing		
Sepsis and ischaemia	22	55
Flap necrosis	4	43
Reamputation	3	18

RESULTS

Mortality was twice as great in the above-knee as in the through-knee group amongst unilateral amputees. The death-rate was very much higher in bilateral above-knee amputees. This is shown in *Table IV* together with the incidence of local complications in the two groups.

The most prominent local complication following amputation was delayed healing which was due to either sepsis or ischaemia or a combination of the two. Many more of the through-knee amputees suffered flap necrosis than did their above-knee counterparts. The converse was true as regards infection. The predominant organisms causing infection in both groups were *Staphylococcus aureus* coagulase positive, *Staphylococcus albus*, and *Bacillus proteus*. However, in only 1 patient in whom *Staph. aureus* was isolated from the wound was *Staph. aureus* also found on the nasal swab. It will be seen from *Table IV* that the rate of delayed healing was over twice as high in the through-knee group of amputees as in the above-knee group. It is not surprising to find, therefore, that the rate of conversion of a through-knee amputation to the above-knee type was higher than the rate of reamputation in the above-knee group.

The average time from operation to discharge from hospital was approximately the same in both groups of unilateral amputees, namely 50 days in the case of above-knee amputees and 48 days in the case of through-knee amputees. In the bilateral group, however, the above-knee amputees spent twice as long in hospital as did their through-knee counterparts, above-knee amputees remaining in hospital for 141 days as opposed to 64 days in the case of the bilateral through-knee amputees. The average time taken to complete walking training on both temporary and permanent prostheses was very similar in both unilateral above- and through-knee amputees. In the case of the temporary prosthesis the through-knee amputees took 16 days as opposed to 19 days in the above-knee group. Similarly, on the permanent prosthesis the through-knee amputees took 9 days as opposed to 12 days for the above-knee amputees.

Eleven through-knee amputees were lost to follow-up. Of the remainder, 55 per cent of the patients had died in a mean follow-up period of 4·2 years. Of the above-knee amputees who were discharged from hospital, 17 were lost to follow-up. Thirty-four per cent of the remainder had died in a mean follow-up period of 5·9 years. The high late mortality of both groups is an indication of the severity of their associated vascular disease and may partly explain the high operative mortality.

Objective assessment of the walking ability both on the flat and on obstacles such as stairs of a group of above- and through-knee amputees who had completed their walking training on the permanent prostheses showed a much greater degree of freedom of movement in the through-knee group of unilateral amputees. The through-knee amputees were able to walk without aids such as sticks except on rough ground, whereas most of the above-knee amputees needed at least one stick at all times. Hitching of the prosthesis was much more evident in the above-knee group of amputees. All the through-knee amputees interviewed had had phantom limb pain, but some of the above-knee amputees were free of this complaint. It was intermittent in all cases and was rarely troublesome. All the patients in both the above- and through-knee groups showed deterioration in their walking ability since completing their walking training owing to the development of some bad habits as far as their walking technique was concerned.

DISCUSSION

In view of the high mortality of amputation great care should be exercised in the preparation of the patient. The postoperative mortality-rate of the through-knee amputation was lower than that of the above-knee amputation. Although these patients were not randomly sampled and therefore are not strictly comparable, the higher late mortality in the through-knee group than in the above-knee group and the similar age distribution and incidence of other diseases suggest that the amputees in the through-knee group were no fitter than those in the above-knee group. It is therefore suggested that the through-knee amputation is the safer operation. In common with other published series of amputations (Taylor, 1967) it has been found that the local complication rate is much higher in the through-knee group of patients. In our experience it is only necessary to make flaps of equal length in designing a through-knee amputation. The fashioning of a long anterior flap which has been recommended by Batch and others (1954) jeopardizes the blood-supply of the distal end of the flap and therefore enhances the likelihood of delayed healing of the wound. When equal flaps are cut the resultant scar still tends to lie posteriorly owing to the different elasticity of the patella and popliteal skin. It is therefore felt that the use of flaps of equal length may help to reduce the local complication rate in the through-knee amputation. The better walking ability of through-knee amputees suggests that when it is possible a through-knee amputation should be performed in preference to an above-knee amputation. In view of the deterioration in walking ability in both groups of amputees some form of 'refresher course' in walking technique might help to maintain mobility.

THE EFFECT OF OBSTRUCTIVE JAUNDICE ON THE MIGRATION OF RETICULO-ENDOTHELIAL CELLS AND FIBROBLASTS INTO EARLY EXPERIMENTAL GRANULOMATA

BY EMANOEL LEE

NUFFIELD DEPARTMENT OF SURGERY, RADCLIFFE INFIRMARY, OXFORD

SUMMARY

Clinical and experimental evidence indicates that obstructive jaundice inhibits the healing of wounds. Experiments in the rat designed to investigate the migration of reticulo-endothelial and fibroblasts into experimental granulomata are described. Standard preparations of obstructive jaundice and controls were devised using Wistar rats. The effects of bile-duct obstruction and sham ligation are described. In another group of animals which was similarly prepared granuloma-pouch experiments were carried out by burying sterile cotton-wool pledgets of a known weight. These pledgets were removed from the jaundiced and control animals on the third, fifth, seventh, and ninth days after implantation, dried to remove the fluid component of the inflammatory process, and weighed on a microbalance. The weights were compared and it was found that a significant inhibition of weight increase occurred in the jaundiced animals during the first week, suggesting a delay in the migratory activity of reticulo-endothelial cells and fibroblasts.

A HIGH incidence of wound dehiscence and ventral herniation has been observed in patients in whom operations had been carried out to relieve obstructive jaundice (Lee, 1972). Experimental studies have shown that skin wounds in rats with obstructive jaundice were not able to resist a separating stress as well as wounds in control animals and it was deduced that this resulted from an abnormality of the process of collagen deposition. However, the exact mechanism by which jaundice interferes with this process is not known, nor whether other parts of the healing mechanism are affected. In particular, before collagen fibres are deposited in the ground substance the early stage of healing in man and animals is characterized by a massive infiltration and proliferation of reticulo-endothelial cells and fibroblasts into the wound (Schilling, 1968; Alexander, Bossert, McClellan, and Altemeier, 1971). The experiments described in the present paper were carried out to see whether obstructive jaundice interferes with the migratory activity of these cells and prevents their appearance in foreign-body granulomata.

STANDARD RAT OBSTRUCTIVE JAUNDICE PREPARATION AND CONTROLS

It was felt that the anaesthetic and operative trauma used to produce the obstruction might be additional factors other than the jaundice itself which would make normal animals unsuitable as controls. A standard technique of 'sham ligation' of the bile-duct was therefore used to produce a control group of animals.

Materials and Methods.—Three-month-old albino male Wistar rats (no strain number), weighing 250–300 g., were fed on a high-protein diet supplemented with ascorbic acid and vitamin K_1. The surgery was carried out under sterile conditions using anaesthetic ether administerd by the open method.

The chest and abdomen were shaved and each animal was fixed in a supine position on the operating table. The abdomen was cleaned with 1 per cent hibitane in alcohol and, when dry, the operating field was covered with a sterile Steridrape sheet. The abdomen was opened through a midline supra-umbilical incision. The rat has a mobile duodenum which can be brought out of the wound with little difficulty. Gentle traction of the duodenum to the right stretches the free border of the lesser omentum, and in it the two lowest hepatic ducts can be seen uniting to form a long, thin, common bile-duct which lies closely applied to the pancreas for most of its length (*Fig.* 1). The rat has no gall-bladder. The bile-duct was ligated just distal to the junction of the hepatic ducts and divided between ligatures. The abdominal wall was closed with interrupted silk sutures and the edges of the skin were approximated with a subcuticular silk stitch. Two animals died whilst under anaesthesia, but all the others recovered consciousness within 10 minutes after the ether had been discontinued.

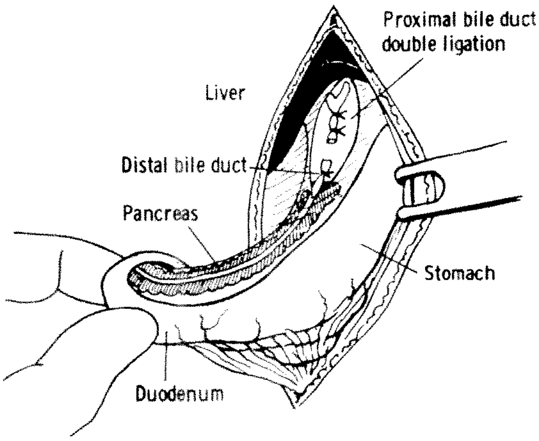

FIG. 1.—Point of ligation of the common bile-duct just distal to the junction of the common hepatic duct.

The control group of animals was prepared by a technique exactly similar to that outlined above except that the bile-ducts were not ligated or divided after being mobilized. Silk ligatures were passed around the duct and then removed. Particular care was taken to standardize the duration of anaesthesia (12 minutes) and the degree of operative trauma.

Wright and Braithwaite (1964) have doubted whether permanent obstruction of the bile-duct can be produced in the rat by ligation of the bile-duct because of 'new channels encircling the obstructed duct'. Restoration of bile secretion into the gut is said to occur within 12 days. The technique described above produced permanent obstructive jaundice in all except 1 animal in whom the ligatures were found to have slipped. Gross dilatation of the duct system proximal to the ligatures was invariably found when the obstruction was permanent. None of the animals became infected.

The Results of Bile-duct Ligation.—The results of obstructing the bile-duct were observed in a series of experiments and compared with the sham-ligated controls. Most animals in both the groups survived the first 6 weeks after surgery without becoming seriously ill. The skin of the obstructed animals became noticeably yellow within 2 weeks and the animals passed dark urine after the first few days. During the first 5 weeks there was no significant deviation of the graphs plotting the weight increases of the two groups of animals. Thereafter the weight of the rats in the control group increased above that of the jaundiced animals.

The serum albumin was measured in 5 normal and in 15 jaundiced rats, killed in groups of 3 at weekly intervals. In both groups the albumin remained within normal limits (*Table I*). Blood was also taken for haemoglobin and prothrombin estimations during the first 4 weeks after operation. One 4-week-jaundiced rat was found to have a low haemoglobin. After 5 weeks of jaundice the haemoglobin showed a tendency to fall below 13 g. per cent (*Table II*). In all the jaundiced animals the prothrombin time was adequately controlled by vitamin-K_1 administration.

Table I.—SERUM ALBUMIN IN NORMAL RATS AND IN JAUNDICED ANIMALS AFTER BILE-DUCT LIGATION

TIME AFTER BILE-DUCT LIGATION	SERUM ALBUMIN (g. per 100 ml.)		NO. OF MEASUREMENTS
	Average	Range	
Normal rats	2·4	1·8–3·2	5
1 week	2·2	1·8–2·4	3
2 weeks	2·6	1·9–3·1	3
3 weeks	2·4	1·9–2·9	3
4 weeks	2·4	2·0–2·6	3
5 weeks	2·6	2·0–3·0	3

Table II.—HAEMOGLOBIN LEVELS IN NORMAL RATS AND IN JAUNDICED ANIMALS AFTER BILE-DUCT LIGATION

TIME AFTER BILE-DUCT LIGATION	HAEMOGLOBIN (g. per cent)	NO. OF MEASUREMENTS
Normal rats	13·4	4
1 week	13·5	3
2 weeks	13·2	3
3 weeks	13·3	3
4 weeks	13·2	3
5 weeks	12·9	3

Thus, a group of jaundiced animals was produced whose health remained relatively normal for at least 1 month after duct ligation and in whom vitamin-C deficiency, anaemia, hypoproteinaemia, and clotting defects had not developed. Subsequent experiments were carried out 4 weeks after duct division or sham ligation—a time when the jaundice was maximal but the general health of the animal was well maintained.

EXPERIMENTS TO ASSESS MIGRATION OF RETICULO-ENDOTHELIAL CELLS OR FIBROBLASTS

Materials.—Dental cotton-wool pledgets manufactured by Johnson & Johnson of Slough were obtained from Messrs Claudius Ash & Sons, 26 Broadwick Street, London, W.1. As supplied the pledgets are non-sterile and 'dry' but it was found that a pledget could contain as much as 3 mg. of water after removal from the packing. Therefore the pledgets were placed in a drying oven at 60° C. for 24 hours to remove the water and the dried pledgets were weighed individually in an Oertling microbalance to the nearest 0·1 mg. Pledgets of identical weight were placed in a glass container for sterilization in a steam autoclave (Baird & Tatlock) at 120° C. and at 1060 g. per sq. cm. pressure for 1 hour. Sterile pledgets in their containers were then placed in a drying oven for 24 hours at 60° C. After drying, the caps of the containers were screwed tight and sealed until the pledgets were required for implantation in the animals.

Technique.—Fifty rats (25 jaundiced and 25 controls) were prepared by the technique outlined above. Twenty-eight days after the initial operation the rats were again anaesthetized and placed in a prone postion and the granuloma-pouch experiments were carried out under sterile conditions.

A 1·3-cm. incision was made across the midline in the skin above the tail. The skin edges were grasped with dissecting forceps and pouches were burrowed subcutaneously on both sides with a curved artery forceps. A sterile pledget of cotton-wool which had been prepared in the manner described above was pushed into each pouch. The incision was closed with a size-20 stainless-steel-wire suture which anchored the skin to the deep fascia. Groups of animals were anaesthetized on the third, fifth, seventh, and ninth days after the creation of the granuloma pouch and the incisions were reopened and the wool granulomata removed. The animals were then killed.

Table III.—Increase in Weight of the Granuloma Pouch in Jaundiced Rats after Bile-duct Ligation and in Control Animals

Time after the Creation of Granuloma Pouch	Jaundiced Rats		Control Rats		Statistical Analysis	
	Weight of Pledget (mg.)	No. of Experiments	Weight of Pledget (mg.)	No. of Experiments	*t*-Test	Level of Significance (per cent)
3 days	7·3 ± 0·6	12	7·8 ± 0·4	10	2·247	95
5 days	7·7 ± 0·9	10	10·0 ± 0·6	14	7·531	99
7 days	6·9 ± 0·8	10	9·4 ± 0·6	10	7·906	99
9 days	10·6 ± 0·9	14	10·3 ± 1·2	9	0·685	None

Each pellet was immediately placed in a siliconized tray and dried at 60° C. for 48 hours, after which time it was weighed to the nearest 0·1 mg. on a microbalance. The change in weight of each pledget was calculated by subtracting the weight before implantation from the final weight. The standard error of the mean of the weights of the pledgets from jaundiced and control animals was calculated. Forty-six satisfactory granulomata developed in the jaundiced animals and 43 in the controls. If pus was found the granuloma was discarded. The increase in weight of the pledgets was compared in the two groups of animals on the third, fifth, seventh, and ninth days after implantation.

Results of Granulomata Weighing Experiments (*Table III*).—The weight increase in the 3-day granuloma of the control animals was found to be higher than the increase in the jaundiced animals and the difference was significant at the 95 per cent range of confidence. A marked difference in weight between the two groups was noted on the fifth and seventh days, but by the ninth day both jaundiced and control animals had weight increases which were not significantly different.

DISCUSSION

The term 'reticulo-endothelial system' was coined by Aschoff and Kiyono (1913) to describe cells which stored vital dyes and took part in the inflammatory process. Fibroblasts have been excluded from the system although they play a very important role during healing (Downey and Weidenreich, 1912). Both reticulo-endothelial cells and fibroblasts migrate into foreign-body granulomata, particularly during the first week of their development, and it is possible that macrophages may be the precursor cells for fibroblasts under some conditions (Barnes and Kruschov, 1968). Selye (1953) devised a 'granuloma-pouch' technique to assay compounds which produce an inflammatory reaction. Croton oil was injected into a pneumatic pouch by the injection of air between the skin and the body wall. Meier, Schuler, and Desaulles (1950) implanted small cotton-wool pellets and then weighed the granulomata which developed. Quantock (1967) studied the microscopic changes during the development of such a granuloma within the cotton-wool and showed that the increase in the weight of the pledget resulted initially from the absorption of tissue fluid and thereafter mainly from the invasion of migrating cells.

In the present experiments a significant inhibition of the expected increase in weight of experimental granulomata was noted in rats with obstructive jaundice when compared with the control animals. The difference in weight of the two groups increased during the first week but by the ninth day no significant difference was found.

CONCLUSION

The results of granuloma-weight experiments suggest that there exists a delay of migration of reticulo-endothelial cells and fibroblasts during the first week of the development of a cotton-wool granuloma in the presence of obstructive jaundice. The abnormality may reflect a defect of cell migration or a decreased availability of such cells during the early part of the inflammatory process in the jaundiced animals. The deficiency in cellular components could account for at least some of the impaired healing which is observed in jaundiced patients.

THE EFFECT OF CLOTHING ON THE DISSEMINATION OF BACTERIA IN OPERATING THEATRES*

By CAROLINE M. DOIG

THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET, LONDON

SUMMARY

The effect of different types of clothing in modifying the dissemination of bacteria was studied in an experimental chamber, using a slit-air sampler to quantify the aerial contamination. Observations were made on volunteers wearing conventional operating-theatre clothing, outdoor clothing, and specially designed theatre wear, both with and without a gown, mask, cap, and boots in all three groups.

The results showed that aerial contamination was least when outdoor clothing was worn. The addition of a sterile theatre gown, mask, cap, and boots reduced this dissemination by half in all the groups. Leaving aside considerations of comfort and hygiene of the staff, it is concluded that outdoor clothing need not be removed before entering an operating theatre (or clean area) provided that a gown, mask, etc., are worn.

THE presence of persons in an operating theatre causes dissemination of bacteria into the environment and this is increased by traffic in the theatre (Blowers, Mason, Wallace, and Walton, 1955). An attempt to reduce this dissemination by modifying operating-theatre wear led to the present study.

The ritual of changing into clean clothes before operating is undertaken for two reasons—the comfort of the wearer and the reduction of bacterial contamination. Duguid and Wallace (1948) found that standard theatre wear did not prevent dissemination of bacteria, but when all the theatre staff wear trousers dissemination is decreased (Bernard, Speers, O'Grady, and Shooter, 1965). Although a correlation between airborne bacteria and wound sepsis has not been proved (Martin, 1967) it is generally assumed that the limitation of bacterial dissemination in the theatre would be worth while. The role of clothing in relation to the dissemination of bacteria into the air has been studied.

MATERIALS AND METHODS

The investigation consisted of determining the bacterial dissemination with various types of clothing under experimental conditions. An experimental polythene tent (560 c.ft.) gave an enclosed but not airtight environment in which to determine the dissemination of bacteria by volunteers (*Fig.* 1). A Casella slit-air sampler (Bourdillon, Lidwell, and Thomas, 1941) was used to determine the aerial contamination quantitatively. Air (at the rate of 1 litre per minute) was drawn through the funnel of the sampler by a soundproof electrical pump on to a revolving blood-agar plate 1 mm. below the slit. The blood-agar plates were incubated at 37° C. overnight and all colonies grown were counted.

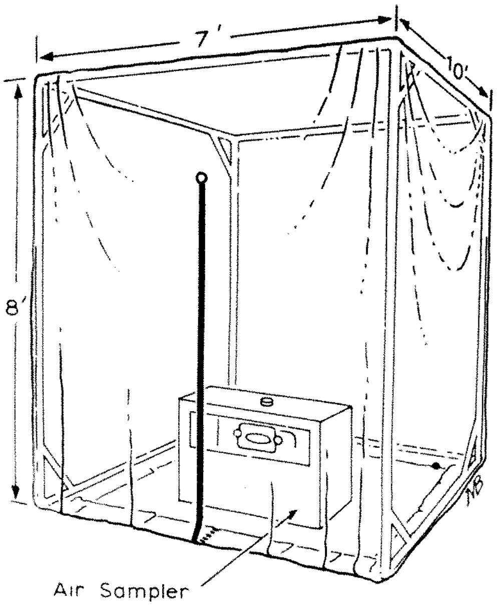

FIG. 1.—The experimental tent with the sampler in situ. Entrance is gained through a long zip in one side of the tent.

Three types of clothing were investigated to determine the amount of bacterial dissemination allowed into the environment:—

1. Outdoor clothing, i.e., ordinary everyday clothing (excluding overcoats).
2. Standard theatre wear consisting of an Aertex shirt and cotton trousers or a short-sleeved cotton shift dress.
3. Specially designed theatre wear. This consisted of thick-weave cotton vests with elastic armbands and cotton trousers with elastic at the waist and anklebands; or a thick-weave cotton frock with draw-string waist and armbands worn over cotton bloomers with elastic at the waist and drawstrings at the thighs (*Fig.* 2). Experiments were carried out with and without the addition of a sterile surgical gown, mask, cap, gloves, and boots.

Control sampling was carried out for 10 minutes when the tent was empty. A volunteer wearing one of the types of clothing then performed a standard exercise in the experimental tent for a further 10-minute sample period. After an hour, during which it was found that the aerial bacterial count fell to almost the control reading, another 10-minute standard exercise period in the tent was sampled while the volunteer wore another type of clothing. This was followed by an hour's rest period, a 10-minute control sample period, and a final 10-minute exercise sample period with the volunteer wearing the third type of clothing. The order of wearing the three types of clothing was random. A further, smaller series of observations was made with volunteers wearing either outdoor clothing or swimsuits.

---

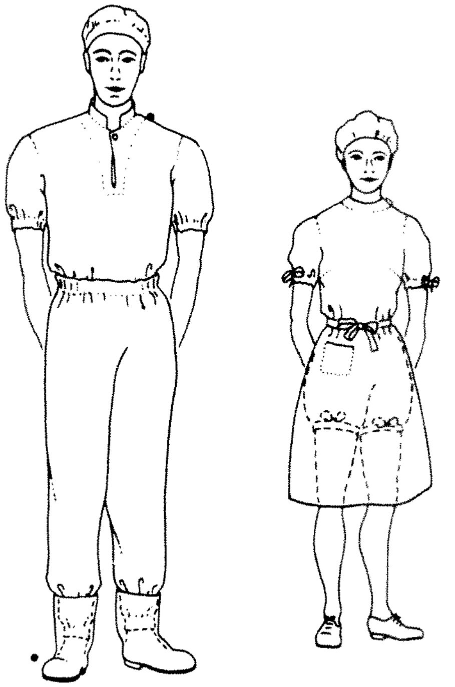

FIG. 2.—The specially designed theatre clothing for both sexes.

RESULTS

Air Sampling in the Experimental Tent.—In the first series of 20 experiments standard exercises were carried out in the tent by a volunteer wearing the three types of clothing in turn; the background colony counts were low, so that a low constant control environment was maintained (*Fig.* 3). Although there was a wide range of results from individual to individual, a difference between the three types of clothing was observed. With outdoor clothing a mean value of 29 colonies per plate per 10 minutes (range, 8–166) was obtained, compared with 72 colonies when our special theatre clothing was worn (range, 8–240), and 73 colonies with standard theatre wear (range, 10–320). Thus, no significant difference in the dissemination of bacteria into the air by either type of theatre wear when worn without gowns was noted ($P > 25$), but there was significantly less dispersal of bacteria with everyday clothing ($P < 0{\cdot}01$).

If in addition to the freshly laundered theatre clothing a sterile gown, mask, cap, gloves, and boots were worn over the clothing, there were variations in the results. During the control periods the counts were again low in these 16 experiments (*Fig.* 4); the lowest mean value for bacterial colony counts under these conditions was obtained when standard theatre clothing was worn, i.e., 16 colonies (range, 4–35). Bacterial dissemination with everyday clothing gave a mean value of 20 colonies per plate (range 6–40), while special theatre clothing allowed a high number of colonies to be dispersed—a mean value of 41 colonies (range 16–99). A significantly higher dissemination of bacteria occurred when special theatre clothing was worn under gowns as opposed to outdoor clothing or standard theatre wear as undergarments ($P < 0{\cdot}01$). If comparisons are made between each type of clothing, with and without gowns, there was a significant decrease in the dissemination of bacteria if gowns were worn over either type of theatre wear ($P < 0{\cdot}01$) (*Fig.* 5). The addition of gowns to outdoor clothing reduced dissemination to a lesser degree ($P < 1$). The reduction in dissemination varied from 32 per cent when outdoor clothing

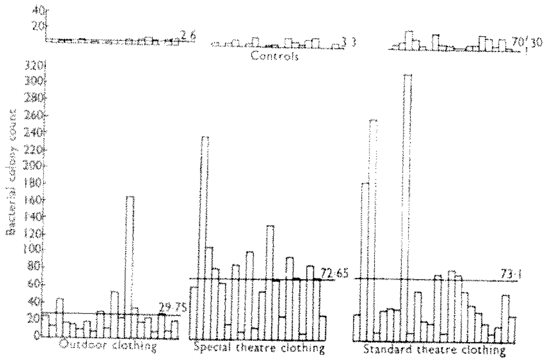

FIG. 3.—The effect of various types of theatre clothing without gowns on aerial contamination. Each block consists of one experiment. Figures indicate mean value. The controls at the top of the figure refer to the control sampling prior to the test period indicated directly below it.

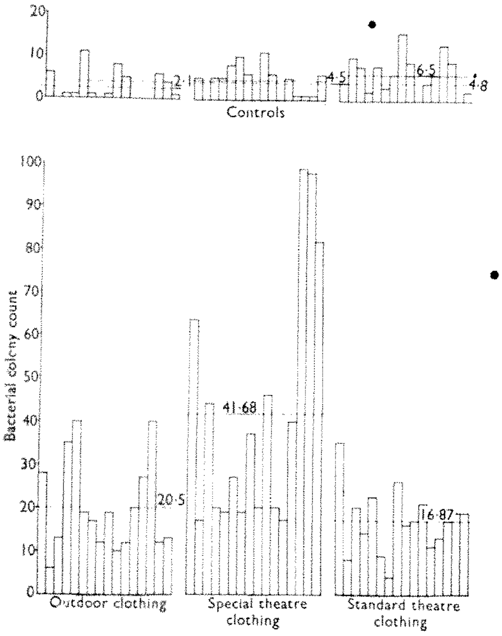

FIG. 4.—The effect of various types of theatre clothing with the addition of sterile gowns, caps, and masks on aerial contamination.

was the undergarment to 42 per cent when special theatre clothing was under the sterile gown, and 77 per cent when standard theatre clothing was the undergarment. It must be remembered that there was no significant difference in the dispersal of organisms when either outdoor clothing or standard theatre clothing was worn with sterile gowns and masks.

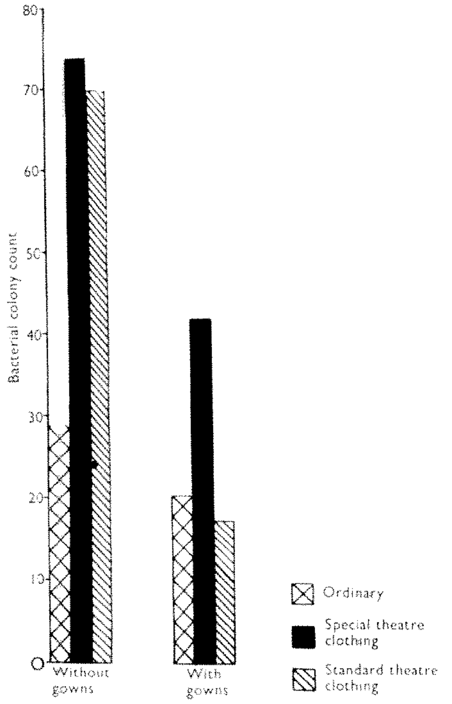

FIG. 5.—Comparison of mean values of aerial contamination for volunteers with and without sterile gowns and masks.

To determine the actual dissemination of bacteria on skin scales when little or no friction is involved a further series of 20 experiments was carried out in the tent. Sampling was performed while volunteers wore either swimsuits or everyday clothing (*Fig.* 6). Background colony counts were again low. Studying the results from the whole group, there was a significantly increased bacterial dispersal when outdoor clothing was worn ($P < 0.02$). However, if males are excluded from the study there was no difference in bacterial dispersal (i.e., swimsuits, 10 colonies per plate; outdoor clothing, 12 colonies per plate). The dispersal of bacteria when wearing swimsuits was similar in both males and females, whereas women in outdoor clothing dispersed fewer bacteria than males similarly clad. However, the numbers in the series were small and further work is necessary to elucidate the results.

DISCUSSION

Activity accentuates the dissemination of bacteria on skin scales (Davies and Noble, 1962). This dispersal of bacteria is not prevented by standard theatre wear and only reduced by 50 per cent by the wearing of sterile theatre gowns (Duguid and Wallace, 1948). The findings in the present study reassert these conclusions, except with regard to theatre gowns worn over standard theatre clothing when the reduction was of the order of 70 per cent. With outdoor clothing under gowns the reduction in dispersal was only 30 per cent. Various attempts have been made to reduce this bacterial dissemination into the environment by operators; the more successful results have been with the use of trousers in the theatre (Bernard, Cole, and Gravens, 1967) and the wearing of a boilersuit type of theatre wear (Blowers and McClusky, 1965).

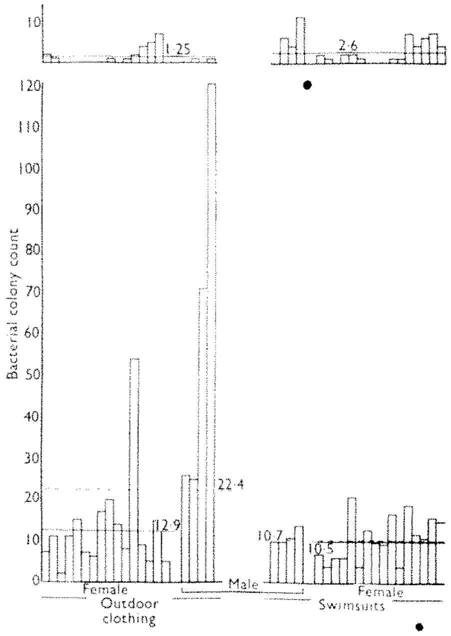

FIG. 6.—Comparison of mean values of aerial contamination for male and female volunteers wearing either swimsuits or outdoor clothing.

Our own design of theatre wear with the addition of bloomers rather than trousers proved less effective in reducing bacterial contamination of the atmosphere. It is likely that the friction of the freshly laundered theatre clothing allowed dissemination of the bacteria-laden skin scales in a similar manner to the counterpane effect demonstrated by Rubbo, Stratford, and Dixson (1962), a view supported by the swimsuit study since, despite extensive skin exposure, there was less contamination. The more numerous layers of outdoor clothing of differing weave material might act to prevent dispersal of scales and so account for the low colony counts for aerial contamination. The abnormal high dispersal with male volunteers in outdoor clothes could be due to the fact that males change their clothing less frequently than females, and so tend to have more scales accumulated in their clothing which if disturbed by friction would increase bacterial liberation. When swimsuits were worn the results for the male were the same as those for the female, indicating again the relationship of friction, scale detachment, and bacterial contamination.

As yet there is no ideal theatre wear that is comfortable, easy to wear, and efficient in preventing the dispersal of bacteria (Medical Research Council, 1968). There would appear to be little value in outine changing into theatre wear apart, perhaps, rom the wearing of sterile surgical gowns, caps, masks, and footwear; although this would seem ufficient for visitors and in special units, it is advisble from the personal hygiene viewpoint for the urgeon to change into fresh clothing.

Acknowledgements.—I wish to thank Professor D. M. Douglas, Department of Surgery, University f Dundee, for his advice and guidance; Professor R. A. Shooter for his guidance in the initial stages; Mr. W. F. Walker and Professor A. W. Wilkinson or their helpful criticism; and also the numerous medical students and medical technicians who helped s volunteers. The experimental tent was made by Oxygenaire and the special theatre clothing by Menzies Ltd., Dundee.

HETEROLOGOUS LIVER PERFUSION

A COMPARISON OF THE USE OF LIVERS FROM FOUR DIFFERENT SPECIES

BY R. HICKMAN, J. R. PARKER, S. J. SAUNDERS, N. E. GOODWIN, AND J. TERBLANCHE

ROM THE DEPARTMENTS OF SURGERY AND MEDICINE, UNIVERSITY OF CAPE TOWN, THE LIVER CLINIC, GROOTE SCHUUR HOSPITAL, THE PROVINCIAL BLOOD GROUPING LABORATORIES, AND THE WESTERN PROVINCE BLOOD TRANSFUSION SERVICE, CAPE TOWN

SUMMARY

Isolated perfusion of livers from calves, pigs, and ambs with human blood resulted in thrombocytopenia within 30 minutes of the establishment of the circuit. No rebound of platelet levels was noted during a urther 3½ hours of perfusion. The levels of total complement and the heterophile antibody titres dropped during the same time in all the experiments. Levels of lymphocytotoxic and leuco-agglutinating antibodies decreased in blood perfusing lamb and pig livers but these were not measured in the calf-liver perfusions.

In contrast, isolated perfusion of livers from baboons with human blood did not provoke significant thrombocytopenia and the results of perfusion were similar to those noted in homologous perfusions of the pig liver with pig blood. There were no differences in platelet levels using livers from baboons with blood groups either compatible or incompatible with the human blood. Complement levels and heterophile antibody titres did not drop and no lymphocytotoxic or leuco-agglutinating antibodies were detectable in human blood against baboon cells.

Measurement of electrolytes, glucose, aspartate transaminase, plasma haemoglobin, and lactate and ammonia clearance showed no significant difference in perfusions of the baboon liver when compared with perfusions of the pig liver with pig blood.

Based on these results, clinical hepatic assist procedures in this hospital will in future only be performed with livers from baboons. These animals will be kept in isolation for a period of virological study in order to minimize the hazard of virus transmission to the patient or personnel.

LIVERS from various animals have been used for hepatic assist procedures in patients with acute liver failure. These include the pig (Abouna, Ashcroft, Muckle, Skillen, Hull, Kirkley, and Hudson, 1970), the calf (Vang and Drapanas, 1966), the baboon (Abouna, Boehmig, Serrou, Amemiya, and Martineau, 1970; Abouna, Fisher, Still, and Hume, 1972), and the human (Sen, Bhalerao, Parulkar, Samsi, Shah, and Kinare, 1966). Recent investigations in this laboratory (Hickman, Saunders, Goodwin, and Terblanche, 1971; Hickman, Parker, Saunders, and Terblanche, 1972) showed that marked thrombocytopenia occurred within 30 minutes of commencement of perfusion of the isolated pig liver with human blood. No subsequent increase in platelets was noted. In addition, complement levels and heterophile antibody titres decreased and lymphocytotoxic and leuco-agglutinating antibodies disappeared during this period. Similar observations had been made in perfusions of the kidney with xenogeneic blood (Pineo, Regoeczi, and Dempster, 1970), but not with the liver.

The thrombocytopenia which had caused clinical assist procedures to be abandoned in this unit (Hickman, Saunders, Harrison, King, and Terblanche, 1971) was thought initially to be due to the inclusion of a bubble oxygenator in the circuit (Hickman, Saunders, and Terblanche, 1969). After investigation in homologous perfusions (Hickman, 1972) further studies were performed with human blood and pig livers and the marked decline in platelets was noted. Since the calf and the lamb had also been used by others for experimental perfusion studies, livers from these animals were perfused with human blood to detect any altered response. In addition, the livers of baboons were investigated. The latter animals may be blood grouped according to the human ABO system using saliva specimens (Wiener and Moor Jankowski, 1963) and the effect of perfusion of the liver with human blood of compatible or incompatible groups was investigated.

MATERIALS AND METHODS

Livers from young calves, lambs, and baboons were removed in a similar manner to that described for the pig liver (Hickman and others, 1969). The organs were flushed with 2 litres of Krebs Ringer bicarbonate solution modified according to Dawkins, Judah, and Rees (1959). The volume distribution through the portal vein was 1·75 litres and through the hepatic artery 0·25 litre. The temperature of this solution was 38° C. (rather than 4° C. as has previously been reported), which appeared to cause a more diffuse wash-out of the liver.

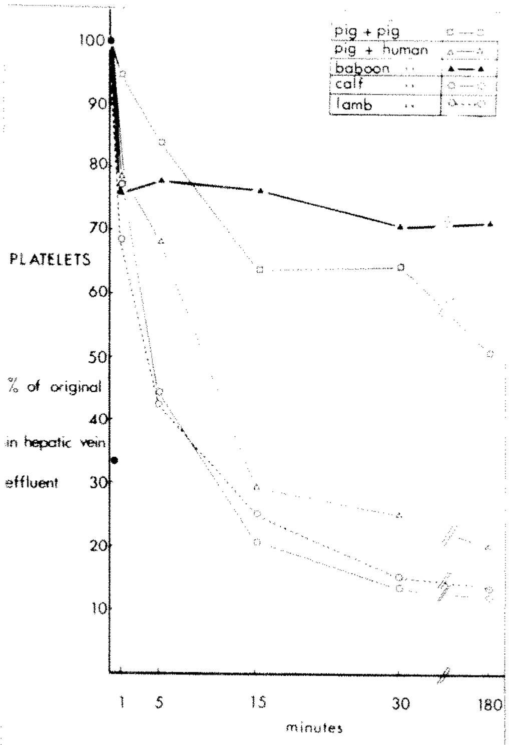

FIG. 1.—The levels of platelets (calculated as a percentage of the initial perfusate level and corrected for small variations in haematocrit) during the perfusion of various animal livers with heterologous and homologous blood.

The organs were inserted into a circuit which was pre-primed with 0·25 litre of McCoy's medium 5A (Hyland Laboratories) and 1·1 litres of fresh heparinized human blood. The mean temperature of the livers upon insertion into the circuit was 26° C. After initial sampling, perfusion was commenced and the livers were warmed rapidly, reaching 38° C. within 15 minutes. During the 4-hour perfusion a continuous infusion was maintained of 150 ml. of 5 per cent dextrose water to which was added 100 U. of soluble insulin, 21 U. of secretin (Boots), and 200 mg. of deoxycholate (Decholin, British Drug Houses) to promote choleresis. Alpha-oxo-glutarate (15 mM.) was added to the flushing solution, the perfusion prime, and the infusion according to the work of Dawkins and others (1959).

Biochemical investigations included the measurement of electrolytes, glucose, aspartate transaminase, ammonia, urea, and lactate/pyruvate ratios, and acid-base analyses, as has previously been described (Hickman, Saunders, Simpson, and Terblanche 1971). Platelets and leucocytes were counted visually by standard techniques, and total complement lymphocytotoxic (Kissmeyer-Nielsen and Kjerbye 1967), leuco-agglutinating antibodies (Boyum, 1968) and heterophile antibodies (Rapaport, Kano, and Milgrom, 1966) against the rat, guinea-pig, and pig were measured. Samples were taken at 1, 5, 15, and 30 minutes, and 1, 2, 3, and 4 hours after perfusion had commenced. After 3 hours a dose of sodium lactate (3·5 g.) and ammonium citrate (2·0 g.) was given and additional samples were taken to determine the rates of clearance.

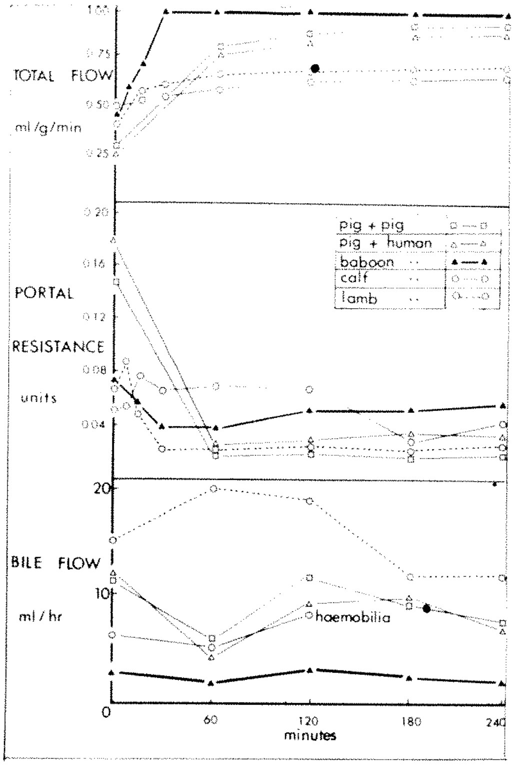

FIG. 2.—The total flow rates, portal resistance, and bile-flow rates during the perfusion of various animal livers with heterologous and homologous blood.

During perfusions the liver was moved rhythmically up and down by mechanical oscillation of the diaphragm.

Three calf and 3 lamb livers were perfused with human blood of group A; 4 baboon livers were perfused with human blood of a compatible group and 5 were perfused with blood of an incompatible group. The latter combinations were livers from groups A, B, and AB animals with human blood of group O, and livers of group B or AB with blood of group A. Human blood of group B is scarce and was not used.

RESULTS

No differences were observed when incompatible human blood was used in baboon-liver perfusions nd hence all the results with baboon livers are combined in the graphs. The following graphs represent the comparative results of the 4-hour perfusions of various animal livers with human blood. The previous results obtained in homologous perfusions of the pig liver with pig blood are presented for comparison.

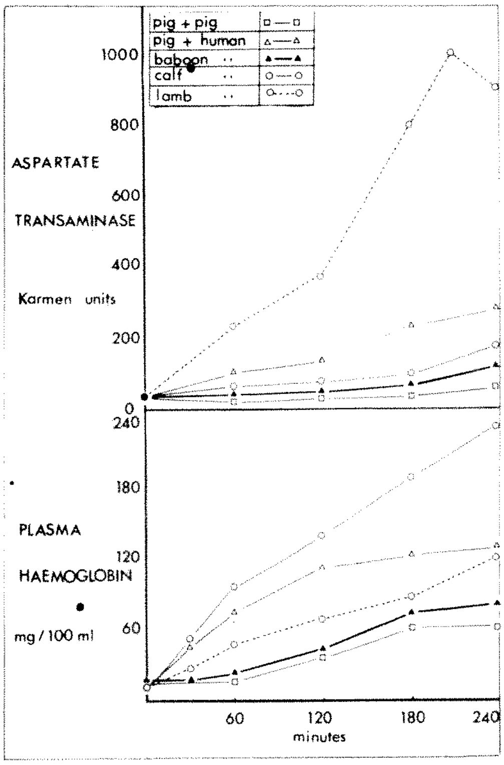

FIG. 3.—The levels of aspartate transaminase and plasma haemoglobin during the perfusion of various animal livers with heterologous and homologous blood.

Table I.—THE PERCENTAGE DECREASE IN COMPLEMENT AND THE PRESENCE AND ABSENCE OF ANTIBODIES DURING THE PERFUSION OF LIVERS FROM DIFFERENT SPECIES

SPECIES OF LIVER	COMPLEMENT (percentage decrease)	ANTIBODIES			
		Heterophile		*Lymphocytotoxic and Leuco-agglutinating*	
		Before Perfusion	After 30 Minutes' Perfusion	Before Perfusion	After 30 Minutes' Perfusion
Pig	28	+	±	4 +	1 +
Calf	47	+	±	N.M.	N.M.
Lamb	40	+	±	4 +	1 +
Baboon	12	+	+	0	0

N.M., Not measured.

The levels of platelets in the hepatic vein samples, calculated as a percentage of the initial perfusate value and corrected for small variations in haematocrit, are shown in *Fig.* 1. A significantly lesser thrombocytopenia accompanied perfusion of the baboon liver with both compatible and incompatible blood ($P < 0{\cdot}001$). The slight decrease seen was similar to that observed in perfusions of the pig liver with pig blood.

In *Table I* it can be seen that the percentage decrease in the complement levels was significantly less when baboon livers were perfused with human blood, and that lymphocytotoxic and leuco-agglutinating antibodies were not detected in human blood against baboon cells. Similarly, heterophile antibodies were not reduced during perfusion. In perfusions of the pig, lamb, and calf livers a marked reduction occurred in the complement and antibody levels. It was found impossible to measure lymphocytotoxic and leuco-agglutinating antibodies in human blood against calf cells owing to an inability to separate lymphocytes and leucocytes from calf blood by standard techniques.

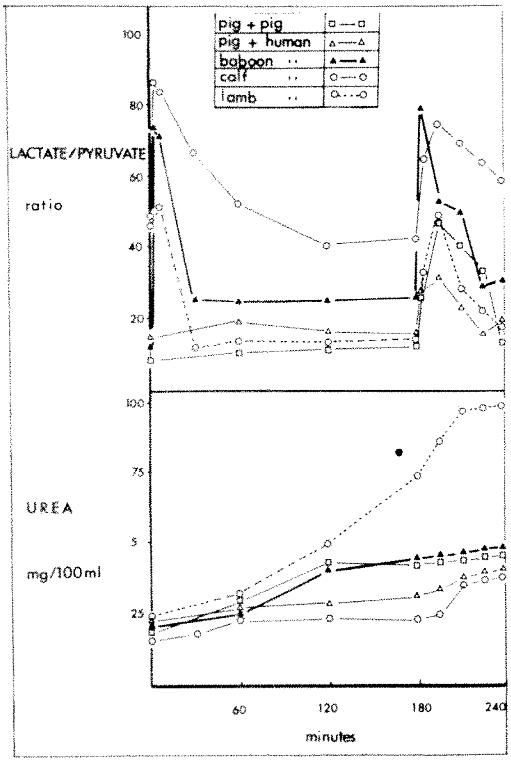

FIG. 4.—The changes in the lactate/pyruvate ratio and the levels of urea during the perfusion of various animal livers with heterologous and homologous blood.

In *Fig.* 2 total flow rates, the portal resistance, and bile-flow rates are shown. It is notable that only in the perfusions of the baboon liver with human blood was the arbitrary optimal rate of flow of 1·0 ml. per g. per minute achieved. This occurred within 30 minutes. The portal resistance in all the experiments was within the suggested 'normal' limits (Eiseman, Knipe, Koh, Normell, and Spencer, 1963) after 1 hour of perfusion. The bile-flow rate from the baboon livers was considerably slower than that in the other liver perfusions, but this might be related to the very small size of the animals (7–10 kg.) since a similar rate was noted intraoperatively.

The rapid rate of bile secretion in the perfusions of the lamb liver and the development of gross haemobilia in the perfusions of the calf liver are notable observations.

The levels of aspartate transaminase and plasma haemoglobin are shown in *Fig.* 3. In all the perfusions except those of the lamb liver the levels of aspartate transaminase did not rise above 300 Karmen units. In the perfusions of the lamb liver a mean final level of 1000 Karmen units was reached. In the perfusions of the calf liver a rapid rise in plasma haemoglobin to 230 mg. per 100 ml. occurred, but in other experiments the highest mean level was 120 mg. per 100 ml.

Fig. 4 illustrates the change in the lactate/pyruvate ratios and the levels of urea. In all the perfusions except those of the calf liver the load of lactate was cleared to preadministration levels within 1 hour. There was a similar increase in urea after the administration of ammonia in all the experiments except those using the lamb liver, where a marked increase occurred.

DISCUSSION

The results show that the isolated baboon liver perfused with either compatible or incompatible human blood does not provoke a significant thrombocytopenia, whereas perfusion of livers from calves, lambs, or pigs resulted in a marked fall in platelets within the first 30 minutes of perfusion. In addition, no obvious adverse biochemical, haematological, or immunological results were noted when the baboon liver was perfused with human blood. When livers from other species were used other evidence of liver damage was noted. Haemobilia occurred during perfusion of the calf liver and a major increase in aspartate transaminase was found during the perfusion of lamb livers. These detrimental effects taken in conjunction with the marked fall in platelets make the use of livers from these animals for clinical assist less desirable in our judgement.

The baboon has previously been used for cross-circulation (Saunders, Terblanche, Bosman, and Barnard, 1969; Hume, Gayle, and Williams, 1969) and no immunological reactions were observed. In addition, experiments in this laboratory have shown that baboons having a total volume replacement with human blood survive normally for 4 days. Only thereafter is there evidence of biochemical and haematological damage (Bosman, 1972). The use of the baboon liver for hepatic assist has been reported with no apparent immunological complication (Abouna and others, 1972).

Thus, in this unit clinical hepatic assist will again be offered as treatment for fulminant hepatic failure, but the livers will be taken from baboons rather than from pigs, calves, or lambs. Owing to the hazard of transmission of virus either to the patient or to personnel (Siegert, 1969) no animal will be used until it has been kept in isolation for 6 months and has been proved repeatedly negative to virological studies.

Warranty

RAY-TEC* X-Ray Detectable Swabs

**Johnson & Johnson Limited (hereinafter called "the Company")
agree to indemnify and hold**

....

(hereinafter called "the Hospital")

harmless for and from any liability, damages, suits, actions, or other injuries it may sustain, in an amount not to exceed £100,000 arising out of and due solely to the failure of any RAY-TEC X-Ray Detectable Swabs to be revealed on an X-Ray plate with standard techniques and equipment.

**This commitment shall … liability, damages, suits,
actions, or injuries … where the personnel
performing a… RAY-TEC X-Ray
Detectabl… exercised
norma… ical and
radi…**

There are some things that you never notice until they are missing…

security is one of them

RAY-TEC* X-ray detectable swabs offer security to the patient, the surgical team – and to the hospital.

For the patient the radio-opaque, barium sulphate impregnated monofilament is soft, non-irritant, non-toxic and unaffected by body fluids.

For the surgical team the presence of the filament can easily be detected even after saturation with blood and exudates.

For the hospital . . .
RAY-TEC* X-ray detectable swabs offer the security of their unique £100,000 indemnity against non-detection on an X-ray plate by standard techniques. This warranty operates in addition to implied warranties under Statute or Common Law.

RAY-TEC* X-ray detectable swabs

IN BRONCHITIS early optimism confirmed by further clinical experience

"On the basis of our earlier experience,[1] we said of trimethoprim that 'we believe it to represent a major discovery and to have far-reaching therapeutic possibilities.' Not only have we had no subsequent reason to alter this belief, but in our view some very promising possibilities have yet to be explored."[2]

More effective than ampicillin or tetracycline

In the reduction obtained in sputum volume and purulence SEPTRIN* has been shown to be superior to either ampicillin or tetracycline.[3,4]

Highly active against both primary and secondary invaders

"... not only are the two primary pathogens *Strep pneumoniae* and *H influenzae* sensitive, but so are secondary invaders such as klebsiella which often replace them after antibiotic treatment."[2]

"It is seldom at the completion of a clinical trial that authors are inclined to classify an antimicrobial ..., but in this case, on our results, we feel that the combination of trimethoprim plus sulphamethoxazole can only be considered excellent on the criteria originally specified, namely the elimination of the infecting microorganism."[5]

ECTOPIC THYMIC TISSUE PRESENTING AS A LATERAL CERVICAL SWELLING

By D. R. A. FINCH and M. H. GOUGH
THE RADCLIFFE INFIRMARY, OXFORD

SUMMARY

Two infants presented with a swelling inferior to the angle of the mandible. At exploration both swellings were identified macroscopically and by frozen section as normal thymic tissue. In the light of present knowledge of the function of this gland in this age-group excision was not performed.

THE thymus is derived embryologically from the ventral outgrowths of the third, and possibly fourth, branchial cleft. As with the thyroid and parathyroid glands aberrations of migration may occur, and thymic tissue has been reported in situations as varied as the base of the skull and the mediastinum at the tracheal bifurcation (Hagens, 1932; Castleman, 1955).

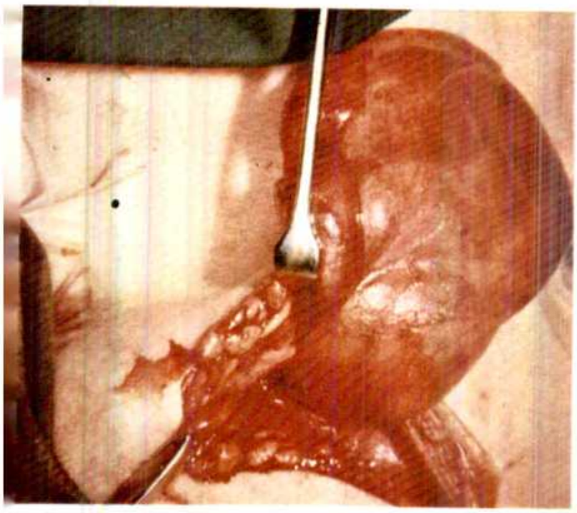

FIG. 1.—*Case* 1. The encapsulated fleshy mass at exploration.

In 1969 Barrick and O'Kell reviewed the literature relating to thymic tissue as a cause of swelling in the neck in childhood and found 43 cases, 40 of which were of thymic cysts and only 3 of normal thymic tissue.

We have recently seen 2 infants presenting with a mass inferior to the angle of the mandible and at exploration both masses proved to be normal thymic tissue.

CASE REPORTS

Case 1.—A. H. was noticed at birth to have a swelling 'the size of a grape' on the right side of the neck. At the age of 4 months the lump was more prominent and was explored under a general anaesthetic. An encapsulated fleshy mass approximately 7 × 5 × 2 cm. was found beneath the platysma, below the angle of the right mandible, and in front of the internal carotid artery, with a vascular pedicle running medially towards the thyroid cartilage (*Fig.* 1). Frozen section revealed normal thymic tissue. The lump was returned to the neck and the skin was closed. A subsequent chest radiograph failed to show a thymic shadow in the mediastinum (*Fig.* 2).

Case 2.—S. H. was noticed shortly after birth to have a swelling 'the size of a gooseberry' below the angle of the right mandible. This was explored at the age of 8 weeks, and a mass approximately 4 × 3 × 3 cm. resembling normal thymic tissue was disclosed (*Fig.* 3). Again, frozen section revealed normal thymic tissue and the lesion was returned to the neck. On this occasion, however, a chest radiograph taken postoperatively showed the presence of a thymic shadow in the anterior mediastinum (*Fig.* 4).

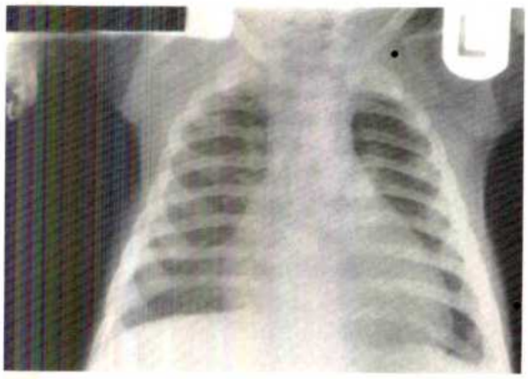

FIG. 2.—*Case* 1. Chest radiograph showing the absence of a thymic shadow in the mediastinum.

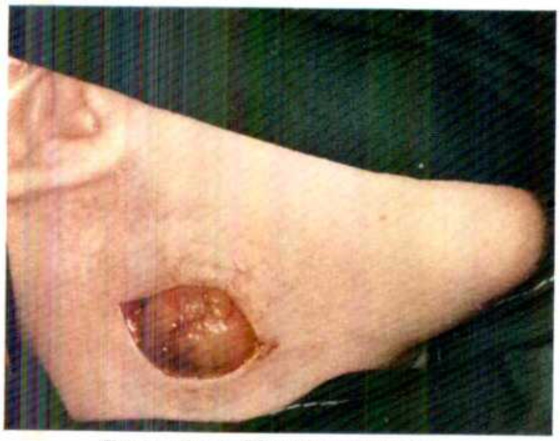

FIG. 3.—*Case* 2. The mass at exploration.

DISCUSSION

The differential diagnosis of a lump in the neck rests between a branchial cyst, a cystic hygroma, or possible malignancy. If there is any doubt on clinical examination exploration is justified at this early age.

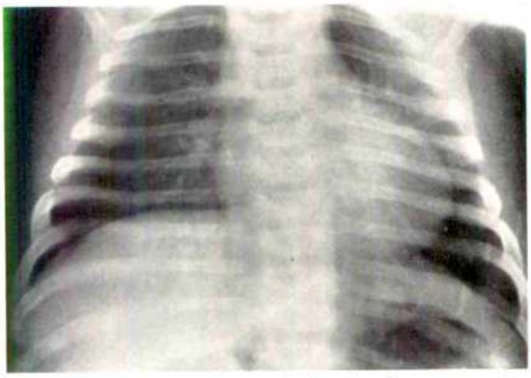

FIG. 4.—*Case* 2. Chest radiograph showing the presence of a thymic shadow in the anterior mediastinum.

It has been well established that the thymus plays an important part in the development of immunological competence. Goldstein and Mackay (1969) in *The Human Thymus* suggest that the stem-cell precursors of the lymphocytes are produced in the bone-marrow, enter the thymus and multiply, and there attain full immunological competence. Any cells which are reactive against the host's own tissues are recognized as such by the thymus and destroyed. The reminder leave the thymus and enter the general circulation through the efferent lymphatics.

Thymectomy in newborn mice results in a rapid reduction of the number of circulating lymphocytes and in depression of the cell-mediated immunological responses, as demonstrated, for example, by failure to reject a skin homograft (Miller, 1962). Thymectomy in other than the neonatal period produces less pronounced effects, but even in the adult mouse, although there is no immediate change, the circulating lymphocyte level and size of the lymph-nodes and spleen have been found to fall after 6 months, and an immunological deficiency develops as demonstrated by the antibody response to bovine serum albumin (Taylor, 1965).

It is not yet known whether these results also refer to man, but there is some evidence that the effects of thymectomy are less in species such as man and dog whose lymphatic system is better developed at birth (Fisher, Fisher, Lee, and Sakay, 1965).

As it is not possible easily to determine whether an ectopic thymic mass represents the whole or only part of the infant's thymic tissue we feel that it is important not to remove this tissue, and in this view we have been supported by the clinical immunologists with whom we have discussed the problem.

The prominence of the thymic swelling can be expected to diminish with growth of the facial skeleton and later with the normal involution of the thymus itself, and this reassuring information can be confidently imparted to the parents once a firm histological diagnosis has been made.

TWENTY-FOUR-HOUR PRESERVATION OF CANINE KIDNEYS EXPOSED TO 45 AND 60 MINUTES OF WARM ISCHAEMIA

BY M. E. SNELL,
ST. MARY'S HOSPITAL, LONDON

W. I. HOPKINSON,
VICKERS RESEARCH ESTABLISHMENT, SUNNINGHILL, ASCOT, BERKSHIRE

AND K. A. PORTER
ST. MARY'S HOSPITAL, LONDON

SUMMARY

This investigation was designed to test the ability of a new hyperbaric organ preservation system to preserve canine kidneys for 24 hours after they had been subjected to significant periods of warm ischaemia. In group I (45 minutes of warm ischaemia) all the kidneys functioned well, and the mean maximum serum creatinine was 4·4 ± 1·7 mg. per 100 ml. In group II (60 minutes of warm ischaemia) 1 dog died on account of acute tubular necrosis. Th mean maximum serum creatinine was 5·4 ± 4·02 mg per 100 ml. The results indicate that hyperbari oxygen warrants serious consideration as an adjunc to organ preservation.

IT is now possible to preserve canine and porcin kidneys for 24–72 hours by a variety of means and t achieve consistent success, provided that the kidneys have been removed under optimal conditions (Belzer, Ashby, and Dunphy, 1967; Collins, Bravo-Shugarman, and Terasaki, 1969; Snell, Hopkinson, and Shepherd, 1972), but attempts to preserve kidneys that have been subjected to a significant period of warm ischaemia prior to preservation have been less successful. Simple surface cooling even for short periods has resulted in sporadic success (Pena, Millard, and Calne, 1971; Quin, Calman, Macpherson, Wood, Deane, McLaughlin, and Bell, 1972). Initial perfusion followed by surface cooling has been no more successful (Frost, Ackermann, Finch, and Manlove, 1970; Scott, Stephens, Keaveny, Kountz, and Belzer, 1971) except where the donor has been pretreated with vasoactive drugs (Løkkegaard, Bilde, Gyrd-Hansen, Nerstrom, and Rasmussen, 1971). Success has, however, been achieved using pulsatile hypothermic perfusion with oxygenated perfusate (Scott and others, 1971; Johnson, Anderson, Morley, Taylor, and Swinney, 1972).

MATERIALS AND METHODS

Mongrel dogs weighing 15–25 kg. were anaesthetized with thiopentone and intubated. Anaesthesia was maintained with an oxygen/nitrous oxide/halothane mixture. The right kidney was exposed through a subcostal incision and mobilized completely. After division of the ureter the renal artery and vein were ligated in continuity. The kidney was replaced in the abdomen and covered by bowel and omentum after which the wound edges were approximated. Forty-five minutes later (group I) or 60 minutes later (group II) the renal artery and renal vein were divided and the kidney was removed. The renal cortex temperature at the end of the ischaemic period was measured with a thermistor probe (Light Laboratories, Model 3GID) and found to be in the range 36–37° C. Phenoxybenzamine, 2·5 mg. in 0·5 ml. of physiological saline, was injected into the renal artery after cannulation. The kidney was placed in a bag surrounded by melting ice and perfused for 5 minutes from a height of 1 m. with a chilled Dextran 40/electrolyte solution (*Table I*). The kidney was then transferred to a Vickers' preservation unit.

Table I.—PERFUSATE COMPOSITION

Substance	*Quantity per litre*
KH_2PO_4	2·05 g.
K_2HPO	7·40 g.
KCl	1·12 g.
$NaHCO_3$	0·84 g.
Dextran 40	50 g.
Dextrose	25 g.
Procaine HCl	100 mg.
Chlorpromazine	16 mg.
Phenoxybenzamine	25 mg.
Heparin	5000 U.
Osmolarity adjusted to 320 ± 5 units with glucose	
*p*H at 20° C.	7·4

After 24 hours the dog was reanaesthetized and a midline abdominal incision was made. The contralateral kidney was excised and following a further injection of 2·5 mg. phenoxybenzamine into the right renal artery the kidney was reimplanted into the iliac fossa, anastomosing the renal artery end to end to the iliac artery and the renal vein end to side to the iliac vein. The ureter was implanted into the bladder using a simple cystotomy and fish-mouth technique.

During the nephrectomy operation 1 litre of dextrose saline was infused intravenously, less than 250 ml. being given prior to ligation of the vessels. In the implantation operation 1·5 litres of dextrose saline and 100 ml. of 10 per cent mannitol solution were infused. Postoperatively the dogs were allowed to drink water *ad libitum* and feeding was commenced on the second postoperative day. Dextrose saline was infused subcutaneously only if vomiting was profuse.

The serum creatinine was estimated daily for 14 days and three times a week thereafter until the dogs were sacrificed on the twenty-eighth postoperative day.

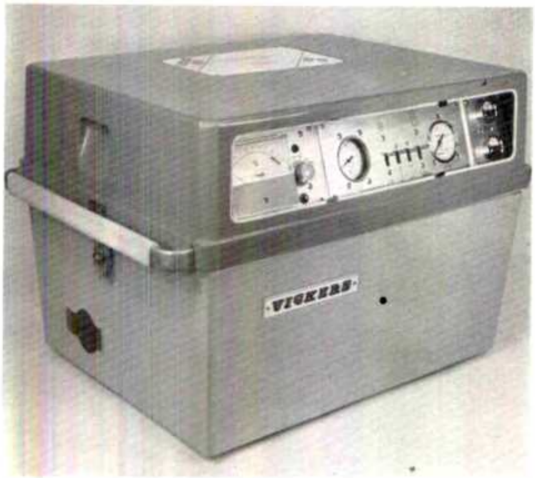

FIG. 1.—Vickers' portable renal preservation unit.

The Apparatus.—The preservation apparatus (*Fig.* 1) has been more fully described elsewhere (Hopkinson, Littlewood, and Snell, 1972). It is a portable device designed to hold a single human kidney and is approximately 60 cm. wide, 40 cm. deep, and 38 cm. high. It weighs approximately 32 kg. The perfusion circuit consists of a gas-driven pump, a 25-μ filter, a membrane oxygenator, and a pressure manometer. The pump is preset to give a predetermined flow rate (2 ml. per minute for canine kidneys) and a maximum output pressure of 80 mm. Hg. Cooling is by means of ice water circulated through a heat exchanger by a small pump. Both the pump and the temperature indicator and controller operate from a 12-V. d.c. dry cell. Supplies of oxygen for the perfusate and nitrogen to drive the perfusion pump are carried in small rechargable cylinders built into the apparatus. The ice reservoir has a capacity of 12–30 hours depending on the ambient temperature and the gas cylinders in excess of 24 hours' duration. The controls are preset to give optimal conditions for the preservation technique described.

Perfusate.—The perfusate is based on Collins's C4 solution (Collins and others, 1969). Magnesium sulphate has been omitted while Dextran 40 and chlorpromazine have been added (*Table I*). The electrolytes are made up in 500 ml. of de-ionized water and autoclaved. A few hours before use heparin, chlorpromazine, and phenoxybenzamine are added and the solution is filtered. Finally, 500 ml. of 10 per cent Rheomacrodex in 5 per cent glucose are added and the osmolality is adjusted with solid dextrose.

Storage Conditions.—In the preservation unit the kidneys were maintained at 5° C. under 310 kN per m.^{2} oxygen. For the first 4 hours the kidneys were perfused at a rate of 2 ml. per minute and thereafter no perfusion took place. During preservation no change in perfusate pH was observed and therefore no monitoring was required.

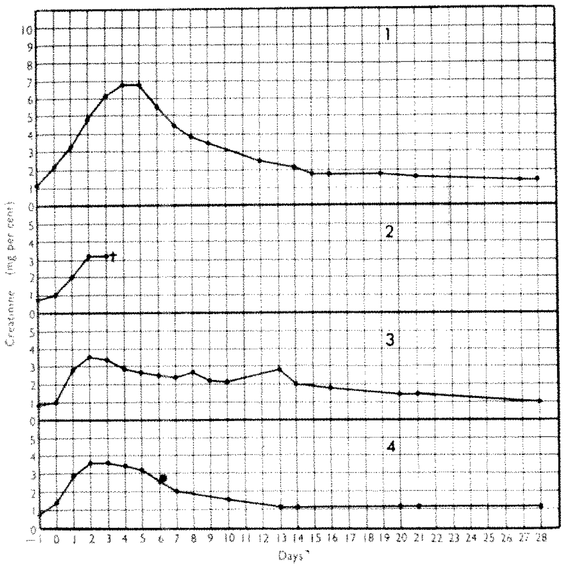

FIG. 2.—Renal function following 45 minutes of warm ischaemia and 24 hours' preservation.

Histology.—Tissue was obtained from all the grafted kidneys either at necropsy or when the dog was sacrificed at 28 days. A portion of each specimen was fixed in formol-saline, embedded in paraffin wax, and stained with haematoxylin and eosin, periodic-acid Schiff reagent, and Weingert's stain for elastic tissue. Another portion was immediately cut into small cubes, fixed in buffered glutaraldehyde, post-fixed in osmium tetroxide, and embedded in Epon 812. Sections, 0·5 μ thick, were cut from these blocks, stained with Azur II, and examined by light microscopy. Very thin sections for electron microscopy were stained with lead hydroxide and examined in a Philips' 200 electron microscope.

RESULTS

Group I: 45 Minutes of Warm Ischaemia.—Three of the 4 dogs in the group survived, with a transient rise in serum creatinine which returned to normal (*Fig.* 2). In 1 of these dogs (No. 4) the renal autograft appeared normal by both light and electron microscopy. No glomerular, tubular, interstitial, or vascular lesions were detected. The grafts from the other 2 dogs (Nos. 1 and 3) were also for the most part normal but both showed a few old, wedge-shaped, cortical scars which were probably caused by pyelonephritis. The scarring was more pronounced in dog No. 1 and had been noted at the time of transplantation. This pre-existing damage probably accounts for the rapid early rise in serum creatinine in dog No. 1 before the reimplantation of the kidney. The fourth dog (No. 2) developed extravasation of urine due to failure of the ureteric implantation and was killed. At the time of sacrifice the serum creatinine had ceased to rise and a return to normal renal function was anticipated. The transplant showed widespread interstitial oedema and dilatation of Bowman's spaces but was otherwise normal.

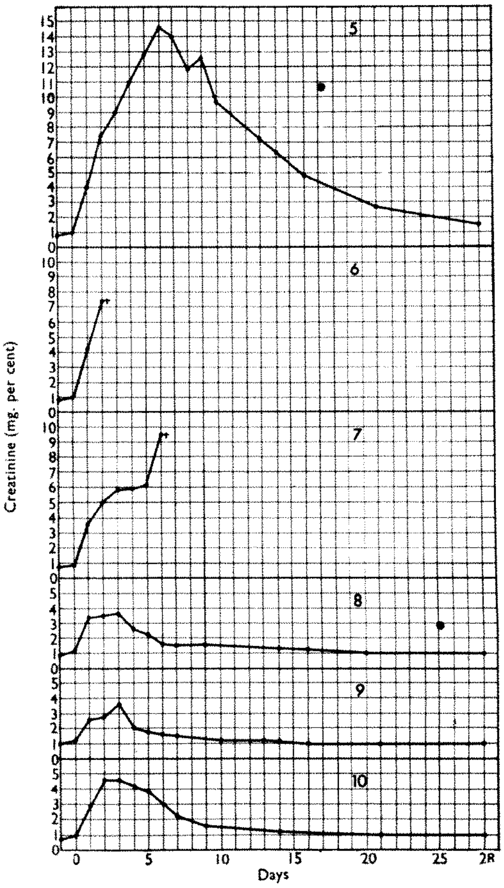

FIG. 3.—Renal function following 60 minutes of warm ischaemia and 24 hours' preservation.

Group II: 60 Minutes of Warm Ischaemia.—In 3 dogs (Nos. 8, 9, and 10) the transplanted kidney functioned well initially and the serum creatinine rapidly returned to normal (*Fig.* 3). All these grafts appeared normal by both light and electron microscopy. In dog No. 5 the kidney underwent torsion during preservation, leading to obstruction of the renal artery. In this animal the early renal function was poor but the serum creatinine had fallen to 1·7 mg. per 100 ml. by day 28. The renal transplant at this time showed many areas of infarction. Dog No. 7 developed a renal artery thrombosis on day 5, up to which time the renal function had been adequate to maintain life. At necropsy the kidney was completely infarcted. Dog No. 6 passed only very small quantities of urine and was killed on day 2. The graft showed widespread proximal tubular necrosis.

DISCUSSION

In cadaveric renal transplantation a period of warm ischaemia inevitably occurs between asystole in the donor and the onset of renal preservation. Wickham, Hanley, and Joekes (1967) demonstrated in the rabbit that increasing periods of warm ischaemia lead to progressively more severe impairment of renal function and that recovery is seldom complete if the period of warm ischaemia exceeds 60 minutes.

Table II.—PERFUSION CHARACTERISTICS OF THE KIDNEYS AND EARLY RENAL FUNCTION

DOG NO.	INITIAL PERFUSION VOLUME (ml.)	MACHINE PERFUSION PRESSURE (mm. Hg.)		MAXIMUM SERUM CREATININE (mg. per 100 ml.)
		Initial	Final	
45 minutes' ischaemia				
1	95	15	10	6·8
2	50	—	—	3·2
3	125	35	16	3·6
4	300	10	6	3·6
60 minutes' ischaemia				
1	92	25	10	14·6
2	85	10	6	7·4*
3	94	9	7	9·5†
4	72	12	11	3·6
5	78	11	10	3·7
6	85	10	6	4·6

* Sacrificed because of anuria.

† Sacrificed because of renal artery thrombosis.

Organ-sharing schemes designed to distribute kidneys on the basis of histocompatibility matching require reliable short-term renal preservation whilst tissue typing and transfer of organs are effected. The present investigation was carried out to test the ability of a hypothermic hyperbaric perfusion system to preserve kidneys subjected to periods of warm ischaemia similar to those encountered in clinical practice.

The initial gravity perfusion resulted in flow rates ranging from 300 to 50 ml. in 5 minutes but there was no correlation between flow rate and early renal function after reimplantation (*Table II*). However, there was a tendency for the flow to be less in the kidneys subjected to the longer period of ischaemia. In previous experiments (Hopkinson and others, 1972) with kidneys which had not been exposed to warm ischaemia the mean flow through 5 kidneys in 5 minutes was 265 ml., which is more than three times the mean volume which passed through the kidneys exposed to 60 minutes of warm ischaemia.

All the kidneys became pink rapidly after revascularization and began to pass urine within 5 minutes with the exception of the kidney of the dog that died of uraemia. After approximately 10 minutes some kidneys became mottled with blue patches but the phenomenon was transient and the kidneys appeared normal within half an hour.

Belzer and Kountz (1970) claim that kidneys which perfuse poorly during preservation function badly on reimplantation and that it is possible to select kidneys suitable for transplantation on the basis of their perfusion characteristics. In the present series we have found both the rate of initial perfusion and the machine perfusion pressure to be unreliable guides to subsequent function (*Table II*).

There have been no reports of repeatedly successful preservation of animal kidneys that had been subjected to 45 minutes or more of warm ischaemia without pretreatment of the donor.

Hartley, Collins, and Clunie (1971) showed in a series of human cadaver kidneys that initial perfusion followed by storage in iced saline slush resulted in immediate function in 24 out of 29 kidneys preserved for up to 12½ hours. In the dog, however, attempts to preserve kidneys after only 15 minutes of warm ischaemia have failed using this technique (Frost and others, 1970; Quin and others, 1972).

The hyperbaric system described here appears to offer an advantage over initial perfusion for the preservation of dog kidneys subjected to warm ischaemia and the results are at least comparable to those achieved with continuous hypothermic perfusion (Scott and others, 1971; Johnson and others, 1972), even though the ischaemic period in the series reported by Scott and others (1971) was only 15 minutes and constant success in the experiments described by Johnson and others (1972) was only achieved after 30 minutes of warm ischaemia. Better results have been reported (Claes and Blohmé, 1970) after 30 minutes of warm ischaemia, but the kidneys were implanted into the neck and kept cool during implantation which may account for the excellent early function. Certainly Dienst and Ansari (1971) have demonstrated that cooling the kidney during reimplantation has a beneficial effect on early postoperative renal function.

The results indicate that the technique described here is satisfactory for preserving kidneys that have been exposed to periods of warm ischaemia acceptable in clinical practice and a clinical evaluation is planned. Furthermore, the results of this investigation employing hyperbaric oxygen are not inferior to those achieved with continuous normobaric perfusion and suggest that hyperbaric oxygen warrants serious consideration as an adjunct to organ preservation.

Acknowledgements.—We wish to thank Mr. F. Littlewood and other colleagues of the Engineering Division, Vickers Research Establishment, and Mr. J. Farrell, Mrs. J. Edwards, and Mrs. J. Reynolds for their excellent technical assistance.

SECONDARY HAEMORRHAGE FROM THE ARTERIAL ANASTOMOSIS OF RENAL ALLOGRAFTS

BY A. J. ROBSON, D. B. EVANS, AND R. Y. CALNE
DEPARTMENT OF SURGERY, UNIVERSITY OF CAMBRIDGE

SUMMARY

Four cases of massive secondary haemorrhage from the arterial anastomosis of a renal allograft as a result of infection are described.

It is likely that the infections developed in the donors and that careful selection is necessary to prevent this. Immediate allograft nephrectomy is suggested as the treatment of choice. The external iliac artery may be ligated without necessarily embarrassing the circulation to the leg.

PATIENTS AND TECHNIQUES

THE donor kidneys were removed aseptically. The kidneys of the donors of *Cases* 1 and 2 were perfused by the method of Schalm (1968), and those of the latter 2 cases by the method of Brunius and Gelin (1966); the kidneys were preserved in ice until used. Renal transplantation was performed by a standard technique (Calne, 1965). Immunosuppression in *Cases* 1 and 2 was as described by Calne, Evans, Herbertson, Joysey, McMillan, Maginn, Millard, Salaman, White, Withycombe, and Yoffa, 1968). *Cases* 3 and 4 received 400 mg. prednisolone on day 1, 180 mg. on day 2, followed by a reduction of 20 mg. per day to 100 mg., and then 10 mg. per day to 50 mg.

The patients were maintained on twice-weekly dialysis and all except *Case* 2 had their own kidneys removed prior to transplantation.

CASE REPORTS

Case 1.—P. N., aged 25 years, was found to have proteinuria in 1960 which was shown on renal biopsy to be due to the nephrotic syndrome. He was treated with prednisone and diuretics. In 1963 his blood-pressure was 170/115 and he was given guanethidine. By 1966 he required haemodialysis. In November, 1966, he received a renal transplant from an 18-year-old male who had died following a road-traffic accident. The donor had been on a respirator for 8 days prior to death. Post-mortem examination revealed bilateral bronchopneumonia.

On the third day after receiving the transplant the patient developed a fever of 39° C. Blood cultures grew five organisms per ml. including *Escherichia coli* on two occasions, and he was treated with ampicillin and ceporin. The urethral catheter which was removed on the tenth postoperative day grew *E. coli* and this organism was also grown from his urine. He was given nalidixic acid and his temperature settled. By the seventh postoperative day he was producing over 1 litre of urine daily.

On the eleventh postoperative day the patient developed sudden pain at the transplant site, passed blood-stained urine, and had a fever. The pain increased and his blood-pressure started to fall. The transplant was explored under general anaesthesia. A massive haematoma was found surrounding the transplant and the arterial anastomosis was bleeding. The artery appeared friable and an attempt to reanastomose it to the external iliac artery was abandoned. The kidney was removed.

Histological examination of the arterial anastomosis showed a necrotic artery wall in which there were numerous Gram-positive cocci arranged in chains.

Postoperatively the patient was treated with chloramphenicol and colomycin and he made a slow recovery which was complicated by a transient mitral incompetence as a result of subacute bacterial endocarditis.

He became fit enough to receive a second transplant in March, 1967, but this contracted a nephrotic syndrome and he developed liver failure, possibly as a result of Imuran toxicity, from which he ultimately died.

Case 2.—R. H., aged 36 years, had a meningomyelocele closed in infancy. In 1966 he developed hypertensive renal failure due to chronic pyelonephritis and required dialysis.

A renal transplant was performed in December, 1966. The donor was a 16-year-old boy who had been involved in a road-traffic accident and who had then been on a respirator for 10 days prior to death. It was subsequently found that he had developed a *Pseudomonas pyocyanea* pneumonia.

A swab taken from the donor artery at the time of transplantation grew *P. pyocyanea* and urine passed on the second postoperative day grew the same organism. Blood culture was similarly positive.

On the thirteenth postoperative day the patient complained of pain and swelling at the transplant site and subsequently his blood-pressure fell. The wound was reopened when considerable clot was found and torrential haemorrhage was seen coming from the anastomosis. Cardiac arrest followed but the heart was restarted following standard resuscitative procedures. The kidney was removed and the defect in the external iliac artery was oversewn. The patient did not resume spontaneous respiration and consciousness did not return. He died 2 days later.

A swab taken from the arterial anastomosis grew *P. pyocyanea.*

Case 3.—P. P., aged 21 years, was a known case of Alport's syndrome (Alport, 1927), his mother having died from this disease and 1 brother also being affected. The patient presented in early 1971 with progressive renal failure and haemodialysis was therefore started.

Renal transplantation was performed in May, 1971. The donor was a 28-year-old female who had died following a drug overdose and who had been on a respirator for 8 days. Subsequently it was found that this donor had had pneumonia from which a *Klebsiella* sp. had been grown.

On the seventh postoperative day the patient complained of pain and swelling in the transplant area and his haemoglobin fell from 6·1 to 4·2 mg. per cent in 24 hours. The wound was explored and bleeding was seen coming from the arterial anastomosis. Arterial sutures were inserted and the bleeding stopped. The wound was closed. A swab taken from the wound at this time grew *E. coli* and urine taken on this day grew a *Klebsiella* sp. with the same sensitivities as that of the donor organism. Postoperatively the patient remained well but he developed a toxic epidermal necrolysis (Lyell's syndrome) and *Staphylococcus pyogenes*, Phage type 71, was grown from his nose and abdominal wound.

On the eleventh postoperative day he bled again and the wound had to be reopened. Bleeding was seen from the Carrel patch and the whole anastomosis was resutured. A wound swab and a specimen of urine again grew *Klebsiella* sp. and he was treated with gentomycin and vancomycin.

A further torrential haemorrhage occurred on the sixteenth postoperative day; the wound was reopened and haemorrhage from the anastomosis was controlled by pressure. The kidney was removed and the external iliac artery and vein were tied above and below the anastomosis. Cardiac arrest occurred, however, following the acute haemorrhage, but the heart was restarted after cardiac massage and standard methods of resuscitation.

Postoperatively the patient did not regain consciousness and he died from pneumonia 32 days after renal transplantation. His leg and foot remained warm at all times and there were no signs of oedema.

Cultures of the anastomosis grew a *Klebsiella* sp. and pyogenic staphylococci, and histology of the Carrel patch revealed a suppurative arteritis, with infection involving the perirenal, hilar, and periureteric tissues.

Case 4.—W. S., aged 45 years, presented with end-stage chronic glomerulonephritis which required haemodialysis from the beginning of 1971. Renal transplantation was performed as a 'double header' with *Case* 3 by another team of surgeons. Both the kidneys for *Cases* 3 and 4 came from the same donor, as described above.

On the nineteenth postoperative day the patient collapsed with acute pain in the transplant area and he became pulseless. He was resuscitated and then the wound was explored when it was seen that torrential bleeding was occurring from the anastomosis. Cardiac arrest occurred and immediate resuscitation was commenced. Normal cardiac function was restored after 20 minutes of cardiac massage. The kidney was removed and the external iliac artery and vein were tied above and below the anastomosis.

Postoperatively the patient made satisfactory progress and he recovered normal consciousness.

He remains alive and well and is back on the haemodialysis programme. Postoperatively he suffered paraesthesia in his left leg and the side of the transplant and the leg was swollen for 3 weeks. This has now resolved entirely, his foot is warm and pink, and he gets no claudication.

A profuse culture of a *Klebsiella* sp. was grown from the arterial anastomosis, the wound, and his urine prior to transplant nephrectomy.

DISCUSSION

Patients receiving standard doses of immunosuppression are particularly susceptible to infection. Fortunately, it is rare for the arterial anastomosis to be infected as described here, this having occurred in 4 out of 139 patients who received transplants in Cambridge between March, 1966, and July, 1971.

In 3 of the patients described here there was a definite relationship between the organism grown in the donor and that in the recipient. In the fourth case (*Case* 1) it was felt that a similar causal relation was likely. In *Case* 2 *P. pyocyanea* was grown from both the donor and the recipient. *Cases* 3 and 4 were transplanted with kidneys from the same donor. Cultures from the donor and both recipients grew a heavy culture of a *Klebsiella* sp. although *Case* 4 was also complicated by staphylococcal infection. All 3 donors had been on a respirator for a week or more. It is suggested that these donors are particularly likely to transmit infection and recipients of such kidneys should be watched carefully for early signs of haemorrhage.

When anastomosis is end to side of a donor Carrel patch to the external iliac artery of the recipient, infection threatens the external iliac artery. It has been known since the time of Astley Cooper (1813) and John Hunter that the external iliac artery or femoral artery can often be tied off in young people without serious nutritional impairment to the leg; this was confirmed in our last 2 patients.

Postoperative wound haematoma from general oozing is not uncommon in renal transplant patients who are undergoing regular haemodialysis involving heparin. Quite distinct from this is massive haemorrhage from the arterial anastomosis. Although rare, this is by far the most alarming complication of renal transplantation both to the patients and to the staff.

In all the 4 cases described here infection was thought to play the precipitating role and in 3 cases it was shown to have been transmitted from the donor.

SURGICAL RESECTION OF RECURRENT CROHN'S DISEASE

By J. L. GROGONO and A. G. PARKS

THE LONDON HOSPITAL

SUMMARY

The outcome of a group of 24 patients having multiple resections for Crohn's disease is presented by means of 'life charts'. These show that it is uncommon for a second resection to be the start of a downhill course and about half of the patients remain well over long periods of follow-up. Comparison with other series is difficult for various reasons, but where comparison is possible the results are similar, except that few patients in this series have so far come to a third resection.

THERE is continuing dispute concerning the place of excisional surgery in recurrent Crohn's disease. A review of the collected series (Kiefer, 1953; Brown and Daffner, 1958; Meyers, Ruble, and Ashley, 1959; Colcock and Vansant, 1960; Gump and Lepore, 1960; Davis, 1961; Stahlgren and Ferguson, 1961; Barber, Waugh, Beahrs, and Sauer, 1962; Barber, Waugh, and Sauer, 1963; Atwell, Duthie, and Goligher, 1965; Colcock and Fortin, 1965; Schofield, 1965; Lennard-Jones and Stalder, 1967; Banks, Zetzel, and Richter, 1969; Brill, Klein, and Kark, 1969) provides conflicting evidence on this question and comparison of one series with another is made difficult by different criteria for recurrence and varying lengths of follow-up, and by the series being selected in different ways in various parts of the world. The 'recurrence rate' in these series varies from 18 per cent (Schofield, 1965) to 73 per cent (Brown and Daffner, 1958), and there is very little comparable information on the patients who had multiple resections. One problem common to all follow-up investigations of Crohn's disease is that the effects of previous bowel excision may mimic recurrent disease:—

Diarrhoea and weight-loss may be due to either the effects of bowel resection or recurrence.

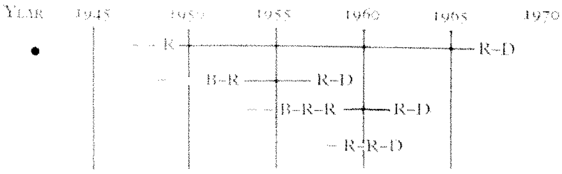
Attacks of abdominal pain and distension may be caused by either adhesion-obstruction or recurrence.

A swelling palpated under an old wound may be due to either scar tissue or recurrence.

A distorted bowel segment seen on barium study may be the result of either the previous resection or recurrence.

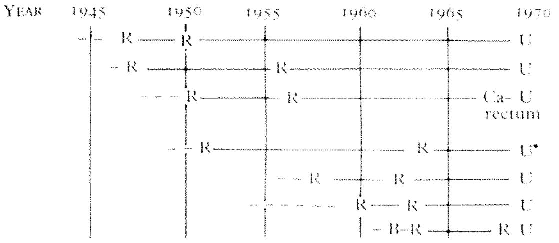
In an attempt to overcome this problem Lennard-Jones and Stalder (1967) classified their cases by the degree of certainty of recurrence; they also analysed their results by construction of life-tables, and a comparison with their results is made later in the Discussion. In the present series the uncertainty in diagnosing recurrence is reduced by case selection; this series concerns only those cases in which both the initial disease and the recurrence have been diagnosed by pathological examination of excised bowel.

Table I.—'LIFE CHARTS' OF 4 PATIENTS WHO DIED FOLLOWING MULTIPLE RESECTIONS



Key to abbreviations: B, by-pass; D, died; R, resection. The dotted lines indicate length of history before the first operation.

Table II.—'LIFE CHARTS' OF 7 PATIENTS WHO WERE 'UNWELL' FOLLOWING MULTIPLE RESECTIONS



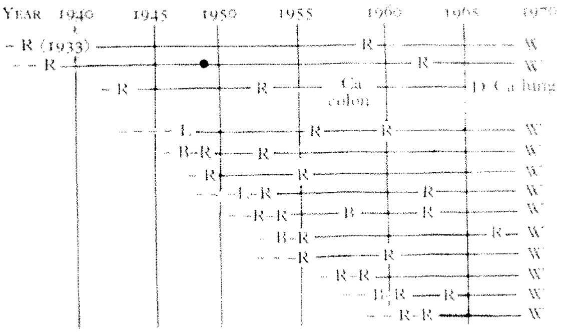
Key to abbreviations: B, by-pass; Ca, carcinoma; R, resection; U, unwell. The dotted lines indicate length of history before the first operation.

PRESENT SERIES

All the cases of Crohn's disease admitted to the London Hospital from 1946 to 1968 have been reviewed; equivocal cases have been excluded. In this series, numbering 152 cases, there were 24 patients who had two or more resections of bowel, with pathological confirmation of the diagnosis on each occasion. Patients in whom the first resection was undertaken less than 5 years previously have been excluded from this long-term study. The case histories of the 24 patients who had two or more resections are shown on 'life charts' (*Tables I–III*). In each of these the dotted line indicates the length of history prior to the first operation. *Table I* shows the histories of the 4 patients who died. All of these patients had enterocutaneous fistulae or complete obstruction (or both) in addition to their recurrent disease, and it is seen that death often followed soon after a surgical procedure in this deteriorating situation.

Table II shows the details of 7 patients remaining 'unwell'. The word 'unwell' reintroduces the uncertainties described earlier, but there is little uncertainty concerning the *initial* recurrence which was resected and the diagnosis confirmed pathologically. No attempt is made to classify these patients as regards the probability of recurrence. However, the 'life charts' show that all except 2 cases have already completed more than 5 years since the second resection without death or further surgery, and the symptoms making some of the patients 'unwell' might be entirely due to the multiple bowel resections. All are being managed as out-patients and only 2 are severely inconvenienced by their symptoms.

Table III.—'Life Charts' of 13 Patients who were Well (or Dead from Unrelated Causes) following Multiple Resections



Key to abbreviations: B, by-pass; Ca, carcinoma; L, laparotomy only; R, resection; W, well. The dotted lines indicate the length of history before the first operation.

Table IV.—A Comparison of the Outcome after a Second Resection for Crohn's Disease in Some of the Published Series

Author	First Resection	Second Resection			Third Resection
		Total	Well	Unwell/died	
Kiefer (1953)	118	28	10	7	11
Meyers and others (1959)	62	7	4	2	1
Barber and others (1963)	82	17	8	4	5
Schofield (1965)	95	18	5	1	12
Lennard-Jones and Stalder (1967)	73	16	5	5	6
Present series (1972)	108	24	12	10	2
Total	538	110	44	29	37
Percentage of second resections		100	40	26	34

Table III gives the histories of the 13 patients who are alive and well (or in 1 case dead from an unrelated cause). In this group all but 1 patient have completed 5 years since the second resection and all were entirely well without symptoms or signs of active disease at the time of the review.

Before discussing these results certain comments must be made on the process of case selection. The patients were selected solely by the common feature of having had multiple resections of pathologically confirmed Crohn's disease. All such cases which occurred in the larger series at the London Hospital are included in this study. However, there are several points which may introduce bias towards a 'favourable' outcome. First, resection of disease implies 'resectable' disease. Although it might seem likely that the 'worst' cases would be included in this study of multiple resections, a few of the most extensively involved cases are excluded by not being resectable, by-pass procedures or conservative treatment being undertaken instead. Secondly, the records are less complete for the patients who died early in the series whereas the notes of long survivors are well preserved. Although all the available records, including microfilmed notes, have been searched, it is easily possible that some early cases have been missed and amongst them a higher-than-average proportion of deaths. Thirdly, there is a source of statistical error in the inclusion of the first 3 cases in *Table III*. They are of particular interest because of the protracted nature of their disease, the average time between resections being 20 years and since the second resection 12 years, and they are included because one resection in each patient was performed during the period of study. Statistically, however, they should be regarded as part of a different population which is not currently reviewed and which includes all the patients having their first resection prior to 1946.

DISCUSSION

There is a sparsity of comparable information concerning the outcome of second resections for Crohn's disease. Even for first resections comparison between different series is difficult, for the reasons outlined earlier, and following second resections the uncertainties are increased. One particular difficulty is caused by the frequent grouping of 'by-pass' and 'resection' cases under a common heading (Brown and Daffner, 1958; Gump and Lepore, 1960; Stahlgren and Ferguson, 1961; Barber and others, 1962; Banks and others, 1969; Brill and others, 1969), and in these series a 'second operation for recurrence' is commonly a first resection, the original operation having been a by-pass procedure. These results are clearly not comparable with the present series; the relatively few series available for comparison are shown in *Table IV*. In view of the small individual numbers only the totals are expressed as percentages. It can be seen that about 1 in 5 of the patients who were subjected to a first resection for Crohn's disease came to a second resection. An exact comparison on this point is possible with the series of Lennard-Jones and Stalder (1967) using the same standard method of actuarial analysis (Hill, 1966). The calculated percentage chance of a second resection at various time intervals after a first resection is shown in *Table V*. This method of analysis is particularly suited to such comparisons since it makes full allowance for varying length of follow-up, patients 'lost sight of' during follow-up, and deaths. The two series are seen to have similar probability figures, as would be expected in generally similar series.

Table V.—Percentage Chance of a Second Resection by Actuarial Analysis in the Present Series compared with that in the Series of Lennard-Jones and Stalder (1967)

Author	Percentage Chance of a Second Resection at Various Times after the First Resection		
	2 yr.	5 yr.	10 yr.
Lennard-Jones and Stalder (1967)	10	16	26
Present series (1972)	6	16	31

The outcome following second resection is shown in *Table IV*, where it can be seen that one-third of the patients came to a third resection, but there are wide differences between series. These variations may be explained by differing surgical philosophies about patients with repeated recurrences, and the numbers are rather small for statistical analysis. The status at follow-up of all the second resection cases has been calculated by combining with the follow-up information of the third resections; it was found that 50 per cent were well, 30 per cent were 'unwell', and 20 per cent have died from complications of the disease or of its treatment. These figures accord with those of other large series which have not been included for lack of comparable information (e.g., Colcock and Vansant, 1960). The length of follow-up will clearly affect the results profoundly; however, long-term follow-up is common in the analysis of multiple resections as the various procedures are often spread over many years. In the present series the average time from the first operation to the review (or death) is 14 years and in most of the series cited the follow-up is at least 5 years.

The decision whether or not to operate for Crohn's disease is often difficult. In general, resection is reserved for patients with severe symptoms or complications and in recurrent disease this conservatism is increased. Some patients inevitably come to further surgery, for example, to relieve obstruction; conversely there are patients who remain entirely well despite recurrence for whom few surgeons would advise reoperation. Between these extremes are patients with 'symptomatic recurrence' in whom many factors will influence the decision. It is towards the management of this group that the present survey may be of some value. There is no evidence that further surgery is frequently the start of continuing complications; if the disease appears well localized and symptoms or complications are severe, then re-exploration with a view to second resection should not be withheld.

THE MANAGEMENT OF CONGENITAL HYDRONEPHROSIS IN THE NEWBORN

BY H. T. WILLIAMS AND K. W. WILKINSON

DEPARTMENT OF UROLOGY, ST. GEORGE'S HOSPITAL, LONDON

SUMMARY

Hydronephrosis due to pelvi-ureteric obstruction rarely presents in the neonatal period. When it does, the disease is advanced and it may be advisable to drain the obstructed kidney until the child is old enough and fit enough to withstand a pyeloplasty. In this paper 2 cases of neonatal hydronephrosis are reported and a satisfactory method of drainage is described.

CASE REPORTS

Case 1.—R. H. was admitted when he was 7 days old with pyrexia and oral thrush. A firm, smooth mass was palpable in the right side of the abdomen which was thought to be of renal origin. The blood-urea was 178 mg. per cent and his urine contained large numbers of pus cells and cultured a mixed growth of organisms. His condition improved with antibiotic therapy, the urine becoming sterile and the blood-urea falling to 52 mg. per cent. An intravenous pyelogram showed both kidneys to be functioning poorly. There was a huge pelvic hydronephrosis on the right side and very little excretion on the left. Under radiographic control right pyelostomy was performed using a large Intracath (*Fig.* 1). After this procedure his progress was very satisfactory (*Fig.* 2). The right kidney maintained a good urine output which was fortunate because little was excreted by the left. Prophylactically he was given rotating antibiotics but these did not prevent *Pseudomonas* organisms appearing in his urine cultures from time to time. During the ensuing 4 months the catheter was accidentally dislodged on two occasions. Each time the child became unwell after a few hours with high pyrexia. The Intracath was reinserted and he was given more powerful antibiotics specific against *Pseudomonas*—on the first occasion gentamycin and on the second carbenicillin. On both occasions he gradually improved over 48 hours. When he was 18 weeks old a Culp-flap pyeloplasty was performed through an anterior extraperitoneal approach. There was no scarring around the renal pelvis and the flap was fashioned without difficulty. It had been hoped to use the catheter to drain the kidney postoperatively but it was dislodged during the operation. The left kidney was found to be atrophic. His postoperative progress was uneventful and he has continued to do well.

Case 2.—A. C. was admitted when he was 4 weeks old for investigation of a left-sided abdominal mass which had been noticed since birth. The baby was otherwise well; the blood-urea was 50 mg. per cent and the urine was sterile. An intravenous pyelogram showed no excretion on the left with delayed excretion on the right outlining a large hydronephrosis (*Fig*. 3). Under radiographic

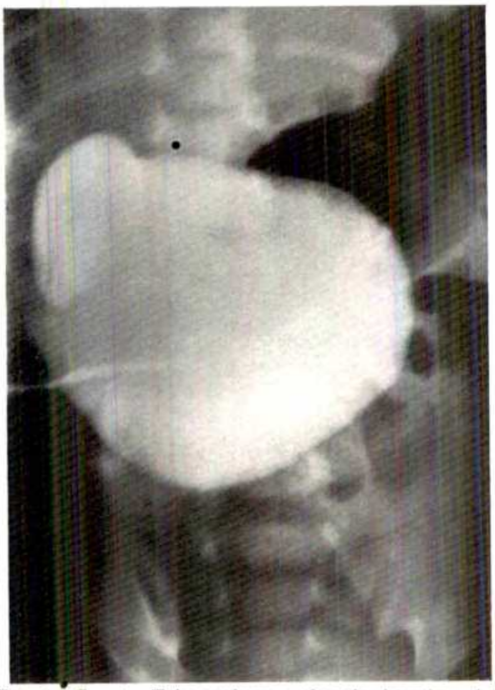

FIG. 1.—*Case* 1. Tube pyelogram after the insertion of the catheter, showing a grossly hydronephrotic right kidney.

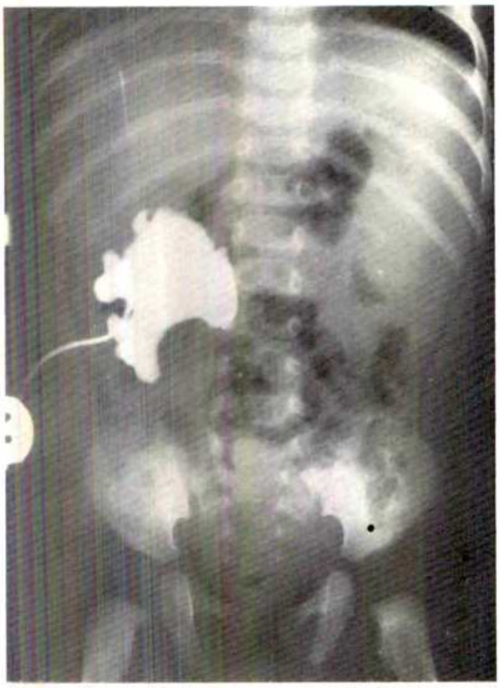

FIG. 2.—*Case* 1. Tube pyelogram 1 month after the insertion of the catheter, showing marked improvement in the degree of hydronephrosis.

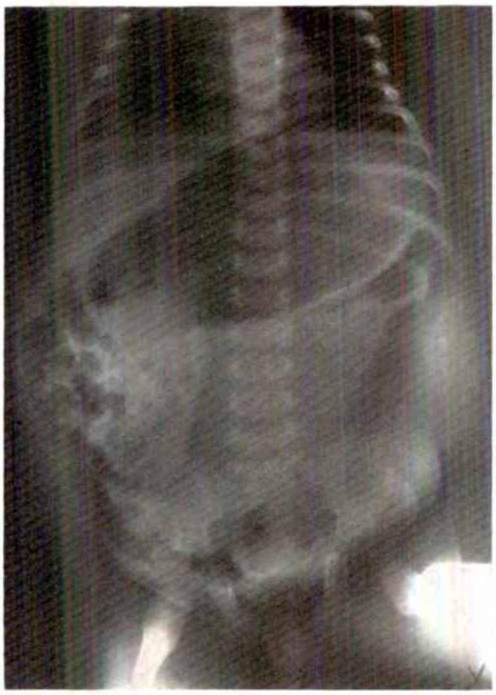

FIG. 3.—*Case* 2. Intravenous pyelogram, showing a large right hydronephrosis with no function on the left side.

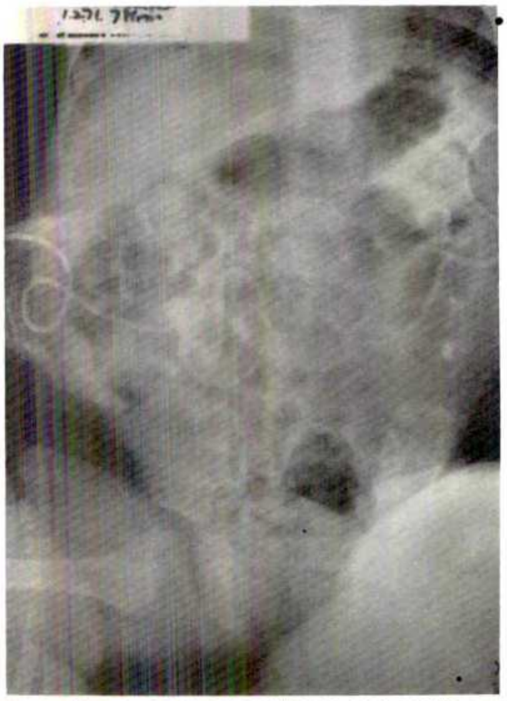

FIG. 4.—*Case* 2. Intravenous pyelogram at 6 months, again showing marked improvement after drainage.

control, an aspiration needle was inserted into the left-sided mass confirming the diagnosis of a large hydronephrosis, and therefore a large Intracath was inserted into each side. Prophylactic Septrin was prescribed. The child progressed very well and as the home circumstances were excellent he was allowed home. After 3 months one of the catheters partially fractured near the skin edge and had to be replaced. This was achieved without any difficulty by changing catheters along a guide wire. This was the only problem encountered with the child's pyelostomy tubes. On Septrin urinary infection was minimal although *Pseudomonas pyogenes* was cultured on occasions from the urine of both kidneys. At 6 months the intravenous pyelogram was repeated (*Fig.* 4). Both kidneys still showed hydronephrosis but there had been a marked improvement. Right Culp-flap pyeloplasty was performed shortly afterwards, using the anterior extraperitoneal approach. There was no scarring around the renal pelvis and the kidney had a reasonable cortex. The catheter was left undisturbed and acted as a drain postoperatively. His subsequent progress was without incident. When urine stopped draining via the catheter and passed all per urethra the tube was removed. The left side was operated on 3 months later using a similar approach and technique. There was a good thickness of renal cortex and again no fibrosis around the kidney. A Culp-flap pyeloplasty was fashioned and the catheter was used as a drain postoperatively. Postoperative progress was again uneventful.

DISCUSSION

Hydronephrosis due to pelvi-ureteric obstruction is relatively uncommon in the newborn. In a 30-year period Uson, Cox, and Lattimer (1968) report 16 neonatal cases out of a total of 130 in childhood. The younger it presents the more severe is the degree of obstruction and the common presenting symptom in the neonate is the presence of an abdominal swelling. Infection may supervene, resulting in further impairment of renal function and subsequent failure to thrive. Williams and Karlaftis (1966) report that 15 out of a series of 26 cases had a palpable mass in the renal area and 7 had urinary infection.

It is important that adequate drainage be instituted early in neonatal cases to conserve as much functioning renal tissue as possible. The disease is frequently bilateral or the unaffected kidney is congenitally abnormal in some other respect. Although initially the hydronephrosis may only be apparent on one side, in a high proportion of cases it subsequently develops in the opposite kidney. Infection in the obstructed kidney can lead to pyonephrosis with rapidly progressive destruction of renal parenchyma.

There is a definite anaesthetic risk attached to major operations in the neonatal period and the hazard to the child is greater if renal function is impaired or urinary-tract infection is present. A temporary drainage procedure would seem to be the treatment of choice, enabling the kidney to function without impediment until the child is old enough and fit enough to withstand a major operation without undue risk; this should be around 5 or 6 months of age. However, if a standard pyelostomy or nephrostomy is performed using a Malecot or similar catheter this involves a partial dissection of the renal pelvis almost as extensive as for a pyeloplasty, and postoperative fibrosis may make the subsequent plastic repair at the pelvi-ureteric junction much more difficult (Eckstein, 1968).

A simpler but equally effective method of drainage has been used successfully in the 2 cases presented here. The child is given a short general anaesthetic and then under radiographic control, using an image intensifier and television monitor a large Intracath is inserted through the flank into the enlarged renal pelvis. Once the pelvis is entered urine flows. Further information can be obtained at this stage by injection of a radio-opaque dye, which outlines the position of the catheter end. Once in a satisfactory position it is anchored to the skin by two silk sutures and also fixed with adhesive strapping. The proximal end of the catheter is connected to a Bardic bile-drainage bag using an intravenous extension tube. All the connexions are made watertight with waterproof adhesive strapping. A useful connexion piece between the catheter and the extension set has been found to be a Galbraith pyelography nozzle.

The subsequent management for the pyelostomy presents few problems. Care must obviously be taken to prevent accidental dislodgement of the catheter. It should be securely strapped to the child in such a position that it causes the minimum of interference with nappy changing, etc., and also where it is not easily accessible to the child's inquiring hand. Should it become dislodged 8–12 hours are allowed to elapse to permit the renal pelvis to fill up again as this obviously facilitates replacement. As the presence of a catheter in the kidney is a potential source of infection the child should have continuous prophylactic antibiotic cover. In this respect Septrin appeared to be the most effective with no side-effects. *Pseudomonas pyocyanea* is the most difficult organism to eradicate, and while normally the presence of this organism caused little concern should the catheter become blocked or displaced an acute fulminating pyelonephritis might ensue. This will produce a high pyrexia and toxaemia which requires treatment with more powerful specific antibiotics.

When the child is considered old enough to withstand the definitive plastic operation an anterior extraperitoneal approach can be used. It will be found that there is no fibrosis around the pelvis to interfere with the pyeloplasty and, whichever method is used, the catheter can be left in situ postoperatively to drain the kidney until the oedema around the suture line has settled.

CONCLUSION

In cases of neonatal hydronephrosis due to pelvi-ureteric obstruction it is important to conserve every nephron since in a high proportion of patients there are associated anomalies of the opposite kidney. The method of drainage described above has been found to be effective and is relatively simple to perform.

Kabikinase®
Streptokinase

Streptokinase
Kabikinase®

Surgical clearance of thromboembolism is often hazardous and troublesome. Clearance with Kabikinase can be a simpler matter, and it often yields superior results : probably because the logic of Kabikinase, highly purified streptokinase, is to potentiate the body's own *natural* ability to dissolve clots.

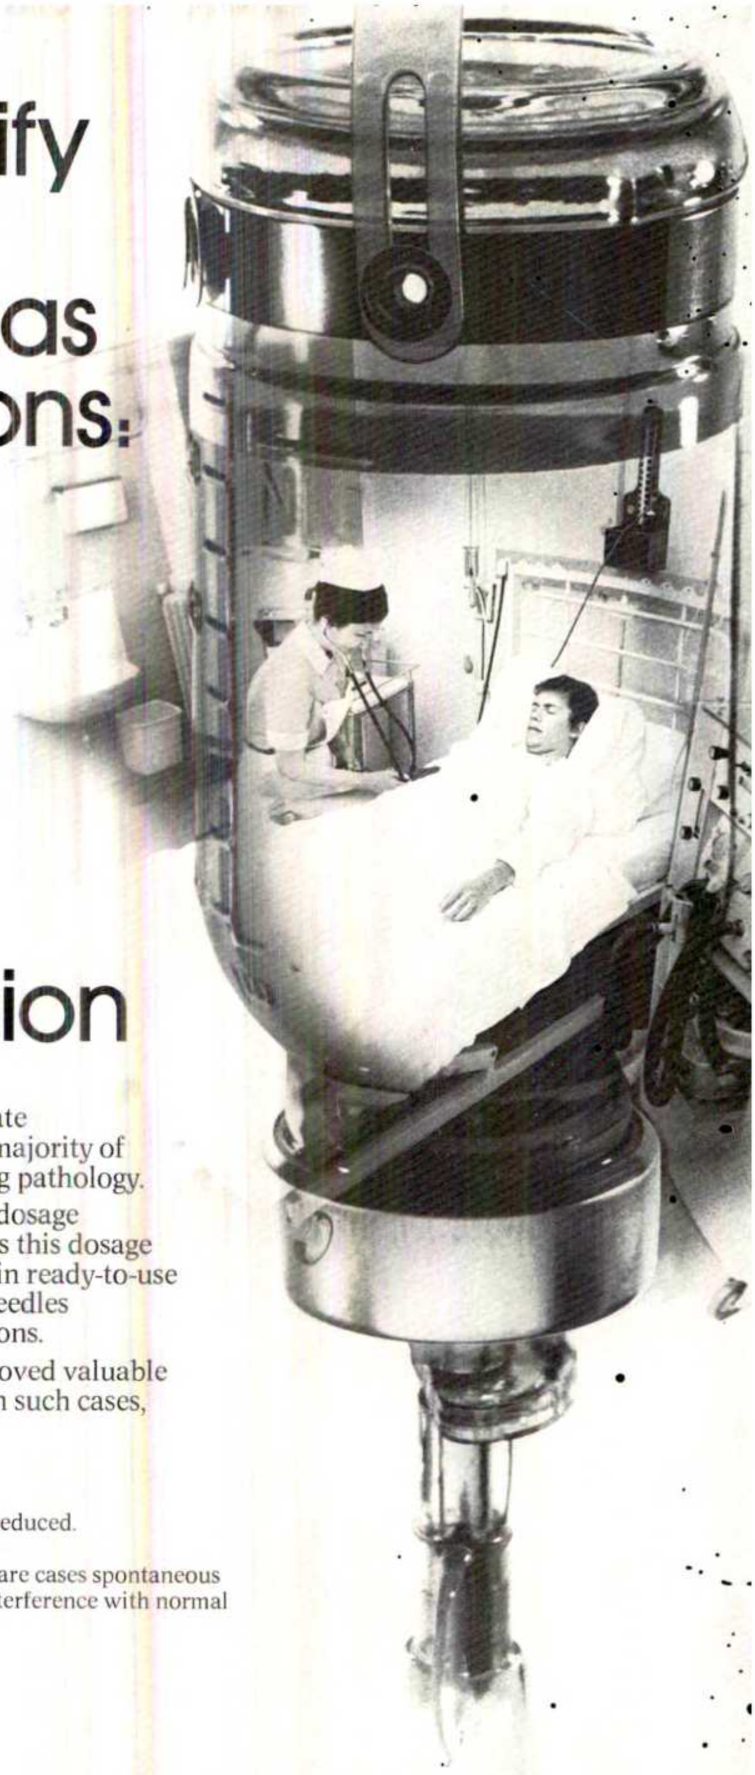
Kabikinase® (pure streptokinase for intravascular infusion) is manufactured by AB Kabi, Stockholm, Sweden and is available only from :

KABI

Kabi Pharmaceuticals Ltd,
Bilton House, Uxbridge Road,
Ealing, London W5 2TH
Telephone : 01-567 4717 or
01-579 1871

A handbook of information about thrombolytic therapy with Kabikinase will be sent on request.

Now, to simplify treatment of pseudomonas chest infections.



Pyopen infusion

n the published papers, Pyopen's success rate in chest infections is 65% even though the majority of he patients described had severe underlying pathology.

The best results have been achieved with a dosage of 20-30G. I.V. daily. Pyopen infusion makes this dosage simpler to administer by providing Pyopen in ready-to-use infusion bottles with diluent and transfer needles for the easier preparation of infusion solutions.

Pyopen is, of course, a penicillin, and has proved valuable n patients with known renal impairment: in such cases, however, dosage should be reduced.

Adult dosage: 20-30G. I.V. daily.
In patients with renal impairment dosage should be reduced.
Contra-indications: Penicillin hypersensitivity.
Side-effects: As with other injectable penicillins. In rare cases spontaneous skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

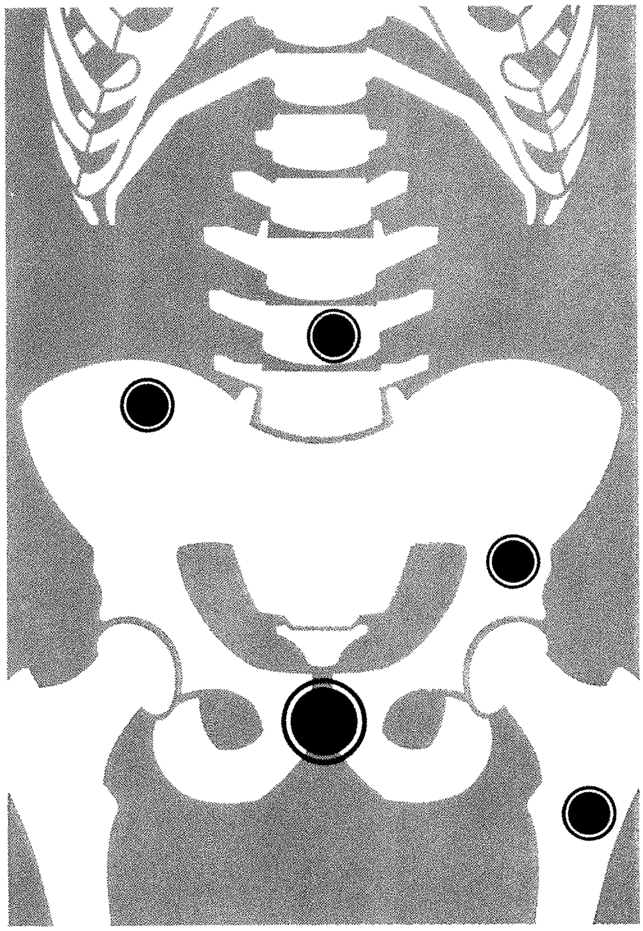
Pyopen

Further information is available on request.
Pyopen* (carbenicillin sodium B.P.) is a British product originated by
Beecham Research Laboratories, Brentford, England. *regd.

Honvan fosfestrol

Honvan is pharmacologically inert until dephosphorylated. It is selectively activated by tissues rich in acid phosphatase, notably the prostate, where it exerts a local cytotoxic action.

Regression of prostatic tumours and metastases is observed in most patients, including a majority of those unresponsive to standard oestrogen therapy.



Response is rapid. **Honvan** is a practical alternati to surgery in acut urinary retention caused by prostati carcinoma.

Gastric tolerance **Honvan** is good and side effects comparatively rar

Honvan is available for both intravenous and oral administratio

a selective cytotoxic action
– in prostatic carcinoma

SURGICAL RESEARCH SOCIETY

A meeting of the Surgical Research Society was held in the University of Liverpool on 14 and 15 July, 1972, with Professor R. B. Welbourn (President of the Surgical Research Society) in the Chair. The following papers were presented:—

1. Experimental Studies on the Influence of the Sympathetic Nervous System on Cerebral Blood-flow: V. D. Deshmukh, A. M. Harper, J. O. Rowan, and W. B. Jennett, Wellcome Surgical Research Institute, University of Glasgow; Institute of Neurological Sciences, Southern General Hospital, Glasgow; Department of Clinical Physics and Bio-engineering, Western Regional Hospital Board.

It is now well established that the cerebrovascular tree is accompanied by sympathetic nerve-fibres (Falck et al., 1968). The present study attempts to elucidate the function of these nerves.

Experiments were carried out in 30 baboons anaesthetized with N_2O, O_2, and phencyclidine and ventilated. Cerebral blood flow (C.B.F.) from the right fronto-parietal area was measured following the intracarotid injection of ^{133}Xe and calculated from the height/area equation (Høedt-Rasmussen et al., 1966). Bilateral cervical sympathectomy was performed about 2·5 cm. below the superior cervical ganglion. The cranial end of the right sympathetic chain was stimulated electrically.

Both sympathetic stimulation and intracarotid infusion of noradrenaline (40 ng. per kg. per min.) had minimal effects on the C.B.F. at normocapnia, but they consistently reduced the C.B.F. during hypercapnia by about 25 and 17 per cent respectively.

On morphological grounds and from physiological data it is argued that there is a dual control of the cerebral circulation, the extraparenchymal vessels being influenced by the sympathetic system while the intraparenchymal vessels are under local metabolic regulation. It seems that the sympathetic control may serve as a protective mechanism in acute episodes of elevated C.S.F. pressure and systemic hypertension.

2. Depression of Delayed Hypersensitivity and Abnormal Bone Scans in 'Early' Cancer of the Breast: D. S. Sumner, M. H. Edwards, and M. Baum (C. T. Howe), Department of Surgery, King's College Hospital Medical School, London.

Delayed hypersensitivity, which may be related to immunity to cancer, is depressed in patients with clinically advanced breast cancer (Mackay and Baum, 1968). Such depression has not been shown in patients with clinical Stage I or II disease, although over 20 per cent of these patients with apparently early cancer have occult metastases which can be detected by bone scanning (Galasko, 1971).

Using strontium 87^{m}, scans of the lumbar spine and pelvis were performed on 40 patients with breast cancer in clinical Stages I and II. Metastases were suggested by the presence of localized areas of increased uptake of the isotope. Delayed hypersensitivity was estimated pre-operatively by the response to an intradermal injection of 5 I.U. of old tuberculin (Mantoux test). A positive Mantoux test was recorded when a skin reaction of 3 mm. or more in diameter was seen at 48 hours.

Of 8 patients with abnormal scans, only 1 showed a positive Mantoux test. The remaining 32 patients had normal scans and the Mantoux test was positive in 16. This difference is significant ($P = 0·01$).

Thus, delayed hypersensitivity appears to be depressed seriously in patients with breast cancer before distant metastases become clinically overt.

3. Intravenous Caloric Requirements: A. O. B. Johnston and R. G. Clark, Department of Surgery, Royal Infirmary, Sheffield.

It has not yet been established whether there is a caloric intake at which there is optimal utilization of a fixed intake of intravenous nitrogen. In this study 26 patients under standard postoperative conditions received 0·23 g. nitrogen per kg. body-weight per day in a D-L-amino-acid mixture. The patients were randomized into four groups having 12, 25, 38, and 51 cal. per kg. body-weight per day. A control group of 5 patients did not receive either the extra calories or nitrogen. Fluid and electrolyte intakes were related to body-weight.

A linear relationship was found between the caloric intake and nitrogen balance ($P < 0·01$). The group receiving 51 cal. per day had a mean cumulative nitrogen balance of $-0·45$ g. nitrogen per kg. body-weight over 5 days as compared with $-1·18$ g. nitrogen per kg. body-weight in the controls. Urinary losses were 7–9 per cent of the infused free amino-acids and 10–13 per cent of the infused sorbitol. The caloric intake had no effect on these losses and it did not affect the cumulative sodium or potassium balances. Sorbitol is a good source of calories and it did not act significantly as an osmotic diuretic.

These results demonstrate that over the range studied nitrogen utilization improves linearly with increasing caloric intake. There was no level of caloric intake at which nitrogen utilization became maximal.

4. Computer-assisted Diagnosis of Abdominal Pain using 'Estimates' provided by Clinicians: D. J. Leaper, F. T. de Dombal, Jane C. Horrocks, and J. R. Staniland, Department of Surgery, The General Infirmary, Leeds.

This paper reports a comparison between two modes of computer-assisted diagnosis conducted as part of a prospective trial involving 472 patients suffering from abdominal pain of acute onset. In the first mode the computer used data collated from a large series of 600 patients. In the second mode the computer analysed each case using 'estimates' of probability provided by a group of 6 clinicians. The accuracy and reliability of the computer in each mode were compared with those of unaided clinicians in the same series of cases.

Using 'real-life' data the computer system was significantly more effective than the unaided clinician (91·1 versus 79·7 per cent accuracy). By contrast, when using the 'estimates' provided by clinicians the computer's overall accuracy (82·2 per cent) was relatively unimpressive and often the computer was *less* effective than the unaided clinician. When individual clinicians' 'estimates' were used the computer's accuracy fell even further.

It is suggested (*a*) that computer-aided diagnostic systems should use 'real-life' data and not clinicians' estimates, and (*b*) that clinicians cannot analyse patients in a probabilistic fashion, since in rarer diseases they have little idea of what the 'true' probabilities are.

5. **Lung Scans, Venograms, and Pulmonary Embolism:** J. J. Spindler, V. V. Kakkar, T. Corrigan, and D. Fossard (C. T. Howe), Department of Surgery, King's College Hospital Medical School, London.

Eighty-four patients with suspected pulmonary embolism were investigated in order to define the accuracy of lung scanning. An attempt was also made to assess whether peripheral venography, chest radiographs, electrocardiograms, and the clinical symptoms and signs could help in the analysis of the lung scans.

Forty-seven patients (56 per cent) had a normal lung scan. Only 5 of these cases had radiographic evidence of deep-vein thrombosis and these thrombi were confined to the tibial and soleal veins. Eighteen patients (21 per cent) had a slightly abnormal lung scan with a low probability of pulmonary embolism. Six of these patients had deep-vein thrombosis and 4 of these thrombi were in the femoropopliteal segment. Eleven patients (13 per cent) had a medium-to-high probability of pulmonary embolism, of whom 9 patients had deep-vein thrombosis and in 5 the femoropopliteal segment was involved. Eight patients (9·5 per cent) had lung scans which were diagnostic of pulmonary embolism. In 4 of these patients pulmonary angiograms confirmed the diagnosis and 2 patients required pulmonary embolectomy. Seven venograms were performed and all showed deep-vein thrombosis.

A lung scan with a perfusion defect of segmental distribution, venograms showing thrombi especially in the large veins of the leg, and a chest radiograph without evidence of an opacifying lesion indicate a diagnosis of pulmonary embolism.

A patient with normal venograms, a chest radiograph showing an opacifying lesion, and a lung scan with a perfusion defect which is not segmental in distribution is very unlikely to have pulmonary embolism.

Lung scanning is simple and reliable, can be repeated, and has no complications. Bilateral peripheral venography is also helpful in the diagnosis of pulmonary embolism.

6. **Absorbable Sutures. A Comparison between PGA and Catgut:** H. H. Wandall, Sv. Holm-Jensen, and Erik Agner, Institute for Experimental Research in Surgery, University of Copenhagen, Denmark.

An absorbable surgical suture has been developed from the synthetic material, polyglycolic acid (PGA).

A study was planned to evaluate the differences in biological behaviour between PGA and catgut with regard to tissue response and the loss of tensile strength during absorption. Different preparations of catgut (plain, chromic, and formalin hardened) were used in the experiments.

The results showed that catgut produces a chronic inflammation lasting for several weeks, a reaction which is absent in the case of PGA. PGA evokes early growth of granulation tissue which invades the thread and destroys it, while catgut becomes surrounded by a fibrotic membrane structure as the chronic inflammatory process subsides. PGA retains tensile strength with only a minor loss (10 per cent) within the first 6 days of implantation but from then on a rather rapid decrease takes place and no strength can be measured at 20–21 days. Catgut loses one-third to one-half of its initial tensile strength within the first 2 days but after this only a slight decline occurs with one-third of its initial strength remaining at 60 days. Great variation was observed. The type of suture preparation is not the decisive factor and the site of implantation determines to a greater extent the fate of the material. Repeated implantation of PGA at 6–7-week intervals causes a change in the cellular response and a massive infiltration of eosinophilic cells appears. Similar findings have not been observed with catgut. The disappearance rate in infected wounds was not significantly different from that observed in wounds without infection.

The new absorbable suture is thus not to be considered a mere substitute for catgut.

7. **A New Principle of Extracorporeal Respiration:** D. G. Melrose (R. B. Welbourn), Department of Surgery, Royal Postgraduate Medical School, London.

Extracorporeal respiration has up till now involved a direct contact between blood and gas in spite of evidence that this interface is responsible for a large proportion of the trauma generated by the method. Attempts to interpose a gas-permeable membrane have hitherto been relatively unsuccessful.

Although suitable membranes now exist (allowing an oxygen diffusion rate of more than 200 ml. O_2 per m.^{2} per min.) the difficulty lies in the geometry of the blood-film itself which may contribute as much as 90 per cent to the overall resistance to oxygenation.

A new device which consists of a number of silicone rubber tubes arranged about the periphery of a wheel relies on the generation of stable vortices within the blood flowing along these tubes when the system is set in oscillatory motion. These spiral vortices almost eliminate the boundary layers normal in axial flow (Melrose, 1972).

In a typical experiment the measured oxygen transport into a stationary tube was 21 ml. O_2 per m.^{2} per min. Oscillation of this tube to produce a movement of the wall relative to the blood within it, at a velocity of 210 cm. per sec., increased the transport to 200 ml. O_2 per m.^{2} per min. Similar considerations apply to carbon-dioxide transport.

A consequence of the oscillatory movement is that blood is induced to move in synchrony with the motion. When the system is equipped with one-way valves this pendulum motion is converted into forward flow and hence a pumping action is created.

Thus the inherent characteristics of the system lend themselves to the development of a self-contained pump oxygenator of simple geometry and very high efficiency.

Melrose, D. G. (1972), *Biomed. Engng*, **70**, 60.

8. **Non-invasive Test of Carotid Blood-flow: its Relevance to Transient Cerebral Ischaemic Attacks:** K. E. Britton, G. Duplock, G. Vaughn-Hudson, D. H. Keeling, and M. M. Bluhm (J. R. Kenyon), Department of Clinical Physics, St. Mary's Hospital Institute of Nuclear Medicine, Middlesex Hospital, London.

Aim: To demonstrate a screening test for abnormalities of carotid blood-flow in man; and whether turbulence of carotid blood-flow is atherogenic.

Method: Collimated scintillation detectors have been designed to view the left and right internal carotid arteries in the cavernous sinuses and to view the root of the aortic arch. Activity/time curves are recorded for 45 seconds after 10–15 mCi 99^{m} technetium is injected intravenously (Britton, 1969).

Results: 1. The activity/time curves determined from the left and right carotid detectors were compared in 89 patients, visually and numerically using a 'carotid index' derived from the take-off point, slope, and peak of these traces. The mean normal value was $0{\cdot}95 \pm 0{\cdot}23$ (1 S.D.); for right and left carotid stenoses values were $< 0{\cdot}49$ and $> 1{\cdot}41$ respectively. Differences ($P < 0{\cdot}02$) were found between 26 'normal' patients and 24 patients with evidence of cerebrovascular disorders. The 2 patients whose symptoms improved after surgery showed a return of the index to normal.

2. The common carotid–internal carotid transfer function has been determined by deconvolution of the output and the input activity/time curves determined from the aortic detector. This spectrum of transit times is used to indicate whether there is laminar or turbulent blood-flow. In turbulent blood-flow, eddying will aid deposition of material from blood and vortices will aid its embolization.

Britton, K. E. (1969), *J. Neurol. Neurosurg. Psychiat.*, **33**, 379.

9. Accelerometry in Gait Analysis: J. R. W. Morris (C. S. B. Galasko), Nuffield Department of Orthopaedic Surgery, University of Oxford.

A technique has been developed for studying normal or pathological movements by direct measurement of acceleration which avoids many of the disadvantages of cinephotography.

Five miniature accelerometers ($\frac{9}{16}$ in. × $\frac{7}{32}$ in. diameter) are mounted on a small Perspex platform. Their positions and sensitive axes are arranged so as to give output signals from which are derived three orthogonal translational accelerations, and two orthogonal angular accelerations. The data are recorded on a purpose-designed pocket cassette tape-recorder. This system allows data to be recorded for up to $\frac{1}{2}$ hr. from any limb segment on an ambulant subject. The recorded tape is played back into a computer for analysis.

Tests have been carried out on the mid-shank of normal subjects where anterior–posterior accelerations in excess of 1 *g* are quite usual in normal walking. Impulsive accelerations occurring at heel-strike are not measured as being significantly larger than those caused by other dynamic movements under muscular control. This situation is maintained during slow running where the foot articulations lengthen the duration of the impulse at toe-strike.

The technique incorporates complete portability and minimum disturbance to the subject.

10. Design Considerations in a New Knee Prosthesis: Paul Aichroth (H. Ellis), Orthopaedic Department, Westminster Hospital, London.

The prosthetic replacement of the knee has proved difficult in clinical practice. The use of large hinge prostheses is complicated by frequent postoperative problems and recently Gunston (1971) has shown encouraging results with a condylar replacement knee prosthesis.

This study explores the possibility of replacing joint surfaces at the knee with prosthetic materials.

The femoral condylar surfaces are replaced with metal components (stainless steel or titanium) and dowels are used to fix the surfaces to the underlying bony bed. Acrylic cement is used for the stabilization of the prosthetic components in bone. The tibial surfaces are replaced with high-density polyethylene components fixed again in a similar fashion with acrylic cement.

Both components are positioned accurately using a jig and the femoral and tibial surfaces are so arranged that rotation of the knee can occur. Other specific advantages are the relatively small size of the prosthesis, the rigid fixation, minimal joint disturbance with retention of the cruciate and collateral ligaments, and the low friction of the system.

Gunston, F. H. (1971), *J. Bone Jt Surg.*, **53**, 272.

11. Measurement of Metacarpophalangeal Joint Torque: A New Instrument: R. A. Dickson, R. Presswell, J. M. Thomas, and J. S. Calnan, Royal Postgraduate Medical School, Hammersmith Hospital, London.

Stiffness at the metacarpophalangeal joint has been measured using a portable arthrograph. This expensive apparatus can only record torque at the index metacarpophalangeal joint. A new instrument, the torque meter, has been developed to measure torque in all fingers of either hand in any position from full extension to 90° of flexion, so that torque can be investigated throughout the entire range of movement of the joint.

The instrument makes use of the principle of the torsion bar. By pressure of the finger on a horizontally attached extension bar, the torsion bar is wound up and the deflexion of the extension bar is registered on a Vernier dial gauge. The torsion bar pivots on the aluminium base and can be locked in any position of rotation, allowing a recording to be made in any position of the joint. Furthermore, the extension bar slides up and down so that any finger can be tested. By calibration against known weights, the movement of the torsion bar is shown to be Hookean.

Torque in normal metacarpophalangeal joints falls gradually in a linear fashion from full extension to 90° of flexion. In the rheumatoid joint with gross synovial proliferation, fall off to zero is rapid, while after synovectomy it returns to the gradual fall off of the normal hand.

12. The Effect of Composition on the Corrosion Resistance of Surgical Stainless Steel: D. F. Williams (D. Annis), Department of Dental Sciences, University of Liverpool.

A new design concept for corrosion-resistant orthopaedic implants has been presented previously (Williams, 1971). This was based upon observations that both design and materials selection controlled corrosion resistance. Further work has now been performed to determine optimum material specifications.

A study of *in vivo* corrosion occurrences has revealed two special features of the composition of stainless steel which influence the corrosion resistance. These concern carbon and nickel. Current specifications recommend a 0·07 per cent maximum for carbon and a range of 10–15 per cent for nickel. However, intergranular corrosion, which is critically controlled by carbon distribution, occurred in implants with less than this maximum. Only when the carbon content was less than 0·03 per cent were the implants immune to this corrosion.

Galvanic corrosion may occur between two components if their metallurgical structures are very different. Nickel has a marked influence on the structure and it was found that substantial structural changes in bone screws occurred when the content was less than 11 per cent.

It is concluded that revised specifications to give a maximum carbon content of 0·03 per cent and a range for nickel of 11–15 per cent will give significantly greater corrosion resistant surgical stainless steels.

Williams, D. F. (1971), *Br. J. Surg.*, **58**, 860.

13. Machine for Dynamic Load Testing of Internally Fixed Femoral Neck Fractures: M. A. Elloy (D. Annis), Bio-engineering and Medical Physics Unit, University of Liverpool.

Internal fixation is the usual treatment for femoral neck fractures. Good fixation permits joint function and holds the fragments in good apposition while osseous union proceeds.

Osteosyntheses have been tested under static load (Hackstock and Hackenbroch, 1969), but as bone deformation is time dependent, dynamic load testing is more appropriate.

A machine has been constructed which applies simulated walking or other physiological load cycles to femurs which are prepared with a 'standardized' transcervical fracture and internally fixed with the implant under test. The magnitude of loads, which are applied along three orthogonal axes, was derived from *in vivo* tests and supplied with air at 5·6 kg. per cm.^{2} pressure. The three pneumatically actuated loading units can produce forces ranging from 0 to 420 kg. with accuracy ±2 kg. and cycle at 0–3 Hz. A number of displacement transducers and a simple analogue computer deduce relative movement of the two fragments during load cycling, measuring up to ±2·54 mm. translation and ±2° rotation with an accuracy of better than 1 per cent. Continuous load cycling permits durability testing.

Dynamic testing will assist the surgeon in choosing an implant from the many available. Without this he must rely on information derived from clinical trials, which are time consuming and often unreliable.

HACKSTOCK, H., and HACKENBROCH, M. H. (1969), *Arch. orthop. Unfallchir.*, **66**, 72.

14. Isolation of Islets of Langerhans for Transplantation: D. R. THOMAS, A. A. GRIEVE, and M. FOX, The Royal Hospital, Sheffield.

The results of whole-gland pancreatic transplantation have been disappointing. Methods of separation using collagenase digestion of pancreas have been described for the isolation of islets for metabolic studies (Howell and Taylor, 1968). In the rat it has been shown (Lacy and Kostianovsky, 1967) that distension of the pancreas as a preliminary to collagenase digestion produced large numbers of islets. Difficulties have arisen over the harvesting of the liberated islets.

A method is described by which relatively large numbers of viable islets are harvested from rat pancreas.

Method: The animals are killed by cervical dislocation, the common bile-duct is identified, and a small polyethylene catheter tied in place. Ten ml. of Hanks's solution are injected to distend the pancreas prior to pancreatectomy. The pancreatic tissue is cut into small pieces and incubated with collagenase in a shaking water-bath. The digested pancreas is washed and transferred to a Petri dish. The vessel is gently agitated, allowing cellular debris to form a suspension which is discarded. The islets remain on the bottom, where they can be easily seen and can be harvested with the aid of a finely drawn Pasteur pipette under the dissecting microscope.

Results: (1) A yield of approximately 350 islets per rat pancreas may be obtained.

(2) Viability of the islets has been confirmed by successful transplantation beneath the renal capsule, and in the testis of the rat.

(3) Early experiments show that transplantation of isolated islets modify the course of streptozotocin diabetes in the rat.

HOWELL, S. L., and TAYLOR, K. W. (1968), *Biochem. J.*, **108**, 17.

LACY, P. E., and KOSTIANOVSKY, M. (1967), *Diabetes*, **16**, 35.

15. The Effect of Intravenous Prednisolone on Survival of Rat Heart Homografts: P. R. F. BELL, R. F. M. WOOD, R. O. QUIN, and K. C. CALMAN, Department of Surgery, Western Infirmary, Glasgow.

Since homograft rejection is initiated by lymphocytes, better immunosuppression following transplantation could conceivably be achieved by destruction of these cells at the time of grafting. Two agents are currently available which rapidly damage lymphocytes, namely large doses of intravenous steroids and anti-lymphocyte serum (A.L.S.). This study was undertaken to evaluate the importance of a single dose of these agents given at the time of transplantation alone or in combination with conventional immunosuppression.

Seven groups of 8 heterotopic rat heart transplants were performed, inbred A/gus rats serving as donors for inbred Wistar recipients. The groups, their immunosuppressive régimes, and the results are set out below.

(1) Controls—no treatment, rejected 7 ± 2 days. (2) Azathioprine and prednisolone (3 mg. per kg.) by daily intraperitoneal injection rejected 14 ± 3 days. (3) A single injection of intravenous prednisolone (15 mg. per kg.) at operation rejected 9 ± 3 days. (4) A single intraperitoneal injection of rabbit anti-rat A.L.S. rejected 16 ± 4 days. (5) A single injection of intravenous prednisolone (15 mg. per kg.) at operation followed by azathioprine and prednisolone as in (2) rejected 29 ± 5 days. (6) A single intraperitoneal injection of A.L.S. (1 ml.) at operation followed by azathioprine and prednisolone as in (2) rejected 33 ± 5 days. (7) A single injection of intravenous prednisolone (15 mg. per kg.) and one intraperitoneal injection of A.L.S. (1 ml.) at operation followed by azathioprine and prednisolone as in (2); all these animals were killed at 65 days without rejection.

These results suggest that large doses of intravenous prednisone or A.L.S. alone or in combination as a single dose immediately after surgery greatly enhance the immunosuppressive effect of conventional drugs. The use of a régime comparable to (5) in 33 human renal transplants has produced a 1-year survival of 85 per cent with 1 death.

16. Solutions for Short-term Organ Preservation: K. C. CALMAN, R. O. QUIN, R. F. M. WOOD, and P. R. F. BELL, Department of Surgery, Western Infirmary, Glasgow.

In the search for the ideal method of short-term organ preservation a variety of solutions has been devised. Of these solutions, the Collins C4 solution and the Gelin technique are widely used. The efficacy of these techniques for organ preservation has not been compared with each other nor have their advantages and disadvantages been defined clearly. The components of each method have been analysed and a solution, superior to both, devised.

The efficacy of the Collins and Gelin technique was assessed using the biologically perfused rat heart model (Calman et al., 1971). Groups of 20 rat hearts were flushed with either Collins's solution or a solution based on Dextran 40 containing 100 U. of insulin per litre (the standard solution). The hearts were stored for 17 hours and their viability assessed. The standard solution gave significantly better results than Collins's technique ($P < 0\cdot01$). The inferior results produced by Collins's solution were related to its high content of potassium.

When the standard solution was compared with the Gelin technique, however, the latter was found to be superior ($P < 0\cdot05$). Further analysis of the Gelin method into its three components showed that its superior performance was related to an initial flush with ½ per cent lignocaine and the addition of lignocaine to the solution. When the standard solution was preceded by lignocaine flush it gave results which were statistically superior to the Gelin technique ($P < 0\cdot05$).

Addition of magnesium to the modified standard solution again improved survival ($P < 0\cdot05$).

CALMAN, K. C., QUIN, R. O. MACPHERSON, S. G., and BELL, P. R. F. (1971), *Br. J. Surg.*, **58**, 865.

17. Effect of Different Preserving Media on the Level of ATP in Canine Renal Cortex:

T. Vincent Keaveny, Aidan O'Boyle, and P. Fitz-Gerald, Department of Surgery, University College, Dublin.

Changes in the energy metabolism of the canine renal cortex were studied during renal flush-out with Ringer's solution (0–4° C.) and with Collins's solution (0–4° C.) by following alterations in renal cortical ATP, ADP, and AMP levels.

Mongrel dogs (15–25 kg.) were studied. Five kidneys were flushed out with each flushing solution, the contralateral kidney in each case being used as a control. Renal flush-out was initiated within 50–55 seconds after nephrectomy and continued for a further 7 minutes.

Kidneys subjected to 55 seconds of warm ischaemia showed a mean fall of 28·9 per cent in the level of renal cortical ATP (resting level: 1·18 ± 0·10 μmol. per g. wet weight; level post-ischaemia: 0·84 ± 0·05 μmol. per g. wet weight).

A mean fall of 26·9 per cent in the level of renal cortical ATP was observed after flushing with Ringer's solution (resting level: 1·08 ± 0·01 μmol. per g. wet weight; level post-flush-out: 0·76 ± 0·05 μmol. per g. wet weight). This solution thus prevents a further breakdown in ATP after exposure of the kidney to 55 seconds of warm ischaemia.

A mean fall of only 1·7 per cent was observed in the renal cortical ATP level after flushing with Collins's solution (resting level: 1·16 ± 0·08 μmol. per g. wet weight; level post-flush-out: 1·14 ± 0·08 μmol. per g. wet weight). The ability of Collins's solution to maintain renal cortical ATP levels may explain its effectiveness as a preserving medium.

18. Hyperbaric Hypothermic Perfusion Preservation of the Ischaemically Damaged Dog Kidney:

R. O. Quin, R. F. M. Wood, S. G. MacPherson, K. C. Calman, and P. R. F. Bell, Department of Surgery, Western Infirmary, Glasgow.

Kidneys obtained in Britain from cadaver donors frequently have warm ischaemic injury in excess of 30 minutes. Most of these organs are stored in ice after an initial flush with a variety of different solutions and anuria from tubular necrosis is common after transplantation. This study was designed to compare the merits of initial infusion and cold storage with hyperbaric hypothermic perfusion of ischaemically damaged canine kidneys.

Dogs in all groups were starved for 12 hours then hydrated with saline (20 ml. per kg. over 30 minutes). No pretreatment of any kind was given prior to removal of the kidney, which was exposed to 40 minutes of warm ischaemia by immersion in a water bath at 37° C. After storage the kidney was transplanted and the opposite organ removed to assess immediate function.

Four groups of animals were studied. Simple surface cooling with ice storage for 6 hours at 40° C. preserved 1 out of 7 kidneys. The Gelin technique with 6 hours' storage at 4° C. preserved 2 out of 6 organs and an initial flush with a modified Perfudex solution successfully preserved only 3 out of 10 kidneys. The fourth group of dog kidneys was again exposed to 40 minutes of warm ischaemia followed by hyperbaric hypothermic perfusion for 24 hours. Using this technique 4 out of 6 organs were satisfactorily preserved with immediate function.

Initial infusion with widely used solutions followed by cold storage is not usually compatible with immediate life-supporting renal function. Hyperbaric hypothermic perfusion using a stable synthetic solution and a commercially available portable machine satisfactorily preserved function in dog kidneys exposed to combined warm and cold ischaemia times comparable to those encountered in human cadaver renal transplantation.

19. Dog Liver Preservation for 13–19 Hours with Collins's Solution and Isoproterenol:

L. Lambotte, J. B. Otte, and P. J. Kestens, Department of Experimental Surgery, University of Louvain, Belgium.

Previous experiments have shown that isoproterenol is of value in the preservation of the canine liver. This drug increases the membrane potential of the isolated perfused dog liver and improves the recovery of membrane potential after a period of anoxia. Addition of isoproterenol to the Ringer–lactate solution used to rinse the liver has extended the preservation of the canine liver from 90 to 180 minutes (Lambotte et al., 1971).

In the present experiments isoproterenol has been combined with Collins's solution (Collins et al., 1969). Two litres of Collins's C2 solution without heparin but with isoproterenol (0·2 mg. per litre) were used to rinse the liver which was thereafter kept in an ice-box. Small doses of isoproterenol were also given to the recipient during the operative period. Survivals longer than 5 days have been obtained in 5 out of 7 consecutive cases of orthotopic transplantation with a total ischaemia time ranging from 5 hours 13 minutes to 7 hours 50 minutes (mean ± S.E., 6 hours 15 minutes ± 24 minutes). The preservation period has been extended to 19 hours (7 dogs, mean ischaemia time 15 hours 30 minutes ± 58 minutes).

All the recipients survived the transplantation and were walking on the first postoperative day, and 5 of them survived more than 5 days. Similar results have never been obtained previously without a complicated perfusion technique. A common mechanism for the action of Collins's solution and isoproterenol is suggested. The reduction of the intracellular sodium concentration may result in a decreased activity of the sodium pump with a reduction in energy requirements.

20. Comparison of Function of *ex vivo* and *in vivo* Livers:

A. Cuschieri, P. R. Baker, and R. Shields, Department of Surgery, Liverpool University.

Assessment of function of the perfused liver prior to its use in hepatic assist or transplantation procedures is usually based on comparison with normal values. However, the 'normal' function of the *ex vivo* liver may not be the same as that of the *in vivo* one.

The function of the *ex vivo* (auxiliary) and *in vivo* (resident) porcine livers sharing the same circulation has therefore been compared in 6 experiments. The auxiliary livers were perfused with blood at physiological rates for 6 hours and function assessed in terms of bile volume and bromsulphthalein (BSP) excretion.

The mean volumes of bile (ml. per 15 min. per 100 g. liver) for the auxiliary and resident livers were 0·57 ± 0·22 (S.D.) and 0·92 ± 0·11 (S.D.) respectively, and this difference was significant ($P < 0{\cdot}01$).

Results from single injection experiments showed that excretion of BSP by the auxiliary liver improved with time. However, continuous infusion of BSP demonstrated that the increase in excretion occurred only during the first 2–3 hours of perfusion. After this a constant output was observed with mean BSP excretion rates (mg. per 15 min. per 100 g. liver) of 3·2 ± 2·0 (S.D.) and 5·6 ± 1·3 (S.D.) for auxiliary and resident livers respectively.

In conclusion, the *ex vivo* auxiliary liver does not function as well as the *in vivo* resident organ even when studied under optimum conditions.

21. Liver Perfusion with Human Blood. A Comparison of Pig, Calf, Lamb, and Baboon Livers: J. Terblanche, Rosemary Hickman, and S. J. Saunders, Departments of Surgery and Medicine, University of Cape Town Medical School, and the Liver Clinic, Groote Schuur Hospital, Cape Town.

The mortality of fulminant hepatic failure remains high despite exchange transfusion. Pig-liver hepatic assist was investigated but led to significant thrombocytopenia. This therapy was halted and reinvestigated in the laboratory, where the isolated pig liver perfused with human blood was shown to provoke a marked thrombocytopenia within 30 minutes. Because of the associated observations this was interpreted as a xenograft response (Hickman et al., 1972). As this phenomenon could not be prevented by pharmacological or physical means, livers from calves, lambs, and baboons were investigated.

All livers were perfused for 4 hours with heparinized human blood. Platelets were counted in hepatic inflow and outflow. Standard biochemical parameters, complement, and antibodies (cytotoxic, leuco-agglutinating, and heterophile) were measured in the hepatic vein blood.

Calf- and lamb-liver perfusions resembled the pig liver with a decline in platelets and a decrease in complement and antibody levels.

Baboon-liver perfusions were markedly different with minimal drop in platelets and no antibodies detected against baboon cells.

Hepatic assist should only be carried out with baboon livers, unless the thrombocytopenia associated with the use of the other livers can be prevented.

22. Studies with a New Anti-secretory Drug (UK 5850) in Rats and Man: B. M. Hogbin, S. P. Cox, P. A. Johnson, R. D. Bugden, A. Bennett, L. G. Pullman, and E. A. Stevens (J. G. Murray), King's College Hospital Medical School, London, and Pfizer Ltd., Sandwich.

A new drug (UK 5850, Pfizer Ltd.) has been studied for its effect on gastric secretion in the anaesthetized rat (Rosenoer and Schild, 1962). UK 5850, 2·5–10 mg. per kg. i.v., caused dose-dependent inhibitions of acid-secretory responses to histamine, pentagastrin, carbachol, human gastrin I, and insulin i.v., and to electric vagal stimulation. Prolonged and sometimes complete inhibition of responses (histamine, pentagastrin, and carbachol only studied) could be obtained with 10 mg. per kg. UK 5850, although carbachol was usually inhibited less than histamine and pentagastrin. Studies in various species and tissues suggested that the activity of UK 5850 was not due to atropine-like activity or to a selective antagonism of gastrin. Administration of UK 5850 5–20 mg. per kg. s.c. to Shay rats produced a marked dose-dependent inhibition of gastric ulceration and acid secretion.

Submaximal gastric acid secretory plateaux were produced with pentagastrin or histamine infused i.v. in normal volunteers and duodenal ulcer patients giving informed consent. Aspiration of gastric juice was stopped for 1 hour when isotonic UK 5850 solution (250, 500, and 750 mg.) was given through the nasogastric tube. The average acid output in the two lowest consecutive 15-minute aspirates 1¼–2¼ hours after giving the drug were compared with the average pre-drug secretory plateau.

The combined results in 20 subjects showed percentage reductions of acid output (±S.E.) of 44±7, 34±7, and 42±8 with 250, 500, and 750 mg. UK 5850 (8, 6, and 6 experiments) respectively, due mainly to a fall in volume secreted. Responses to pentagastrin and histamine were inhibited similarly. These experiments show that orally administered UK 5850 is a weak antisecretory drug in man. Maximal inhibition was only about 40 per cent compared with up to 100 per cent with i.v. administration in rats, owing possibly to differences in secretory mechanism or in route of administration.

Rosenoer, V. M., and Schild, H. O. (1962), *J. Physiol.*, **162**, 155.

23. Studies with a New Gastric Secretory Inhibitor (UK 9040) in the Dog: D. B. Hamer, J. H. Baron, and J. Spencer, Department of Surgery, Royal Postgraduate Medical School, London.

Five dogs were each prepared with a fistula of the innervated main stomach (G.F.) and a denervated gastric pouch (H.P.), and 1 dog with a gastric fistula of a vagotomized stomach. Gastric secretion was stimulated by continuous intravenous infusions of pentagastrin (2, 8, and 16 μg. per kg. per hr.) and histamine acid phosphate (2 μg. per kg. per min.) or by single intravenous injections of insulin (0·2 μg. per kg.). Fifteen-minute collections of secretion were made for 3 hours and the volume, pH, and titratable acidity of the juice were measured.

Single intravenous injections of UK 9040, 2·5 mg. per kg., inhibited G.F. but not H.P. acid secretion in response to pentagastrin 2 μg. per kg. per hr. Doses of 5 and 10 mg. per kg. completely inhibited both H.P. and G.F. secretion, but the dogs vomited after 10 mg. per kg.

UK 9040 was given in capsules to the fasting dogs at various intervals before the injection of the stimulant. Doses of 15–30 mg. per kg. given 4–5 hours before the start of infusions of pentagastrin 2 or 8 μg. per kg. per hr., or histamine acid phosphate 2 μg. per kg. per min., produced complete inhibition of both G.F. and H.P. secretion, and there was similar 100 per cent inhibition of the acid response of the G.F. to insulin, 0·25 μg. per kg. There was less inhibition of acid secretion if the capsules were given only 1–2 hours or 18 hours before the secretory stimulants, or if a lower dose of only 8 mg. per kg. was used.

This new drug is a potent inhibitor of histamine-, pentagastrin-, and insulin-stimulated acid secretion in the dog.

24. The Effect of Burimamide on Gastric Secretion in Man: J. H. Wyllie, T. Hesselbo, and J. W. Black, Department of Surgery, University College Hospital Medical School, and Smith, Kline French Research Institute.

The anticholinergic drugs at present used to inhibit gastric secretion are not capable of suppressing secretion stimulated by histamine or pentagastrin given in maximal doses. For example, atropine in doses of 50 μg. per kg. has been estimated to produce only 22 per cent inhibition of pentagastrin-stimulated secretion (Konturek and Olesky, 1969).

Burimamide, defined as a histamine H$_2$-receptor antagonist, is virtually free from conventional antihistaminic activity but can completely inhibit histamine-stimulated acid secretion in animals (Black et al., 1972).

The action of burimamide has been studied in 6 normal volunteers. Gastric acid secretion was maximally stimulated by either histamine or pentagastrin. These experiments showed that burimamide is also effective in man and that 50 per cent inhibition of maximally stimulated secretion was produced by a blood-level of the order of 15 μmol. The effect on pentagastrin-stimulated secretion was the same as that on histamine-stimulated secretion. Thus, burimamide possesses properties which are not shown by any antisecretory agent previously reported.

In the doses used its effect on maximally stimulated acid secretion is similar to that of vagotomy.

25. Secretin-induced Pyloric Reflux: Verification of the Mathematical Formula for Eliminating Reflux in Gastric Aspirate: R. G. Fiddian-Green, R. C. G. Russell, and M. Hobsley, Department of Surgical Studies, The Middlesex Hospital, London.

It has been claimed that the volume of duodenal contents refluxing into the stomach during gastric secretory studies can be calculated from the relationship between apparent rate of secretion and electrolyte concentration (Gardham et al., 1968). This hypothesis has been tested in 20 subjects: a plateau of maximally stimulated gastric secretion was achieved with intravenous histamine infusion (Lawrie et al., 1964), and reflux then induced by injecting Boots's secretin, 1·0 unit per kg. intravenously. In every study the 10-minute volumes of gastric aspirate increased, enabling reflux to be expressed as the difference between the observed volume and the mean pre-secretin plateau volume. Calculated reflux was obtained from the formulae

$$V_{\mathrm{R}}\,(\text{sodium}) = 7{\cdot}35\,Q_{\mathrm{Na}} - 0{\cdot}044\,V - 4{\cdot}05,$$
$$V_{\mathrm{R}}\,(\text{hydrogen}) = 0{\cdot}575\,V - 4{\cdot}29\,Q_{\mathrm{H}} - 4{\cdot}46 \text{ ml. per 15 min.},$$

where V is the volume and Q the ion output in mEq./10 min. sample. Both formulae gave equivalent results ($R = 0{\cdot}83$, slope $= 1{\cdot}1$, intercept insignificantly different from zero) and the sodium formula was shown to give a measure of the change in volume of pure duodenal juice refluxed. These results suggest that the calculation method is a valid approach to the estimation of reflux in gastric juice.

26. The Effect of Antral Denervation and Pyloroplasty on Gastric Emptying and 'Dumping': R. J. Clarke and J. Alexander Williams, The General Hospital, Birmingham.

To assess the effect of antral denervation and pyloroplasty on gastric emptying 40 male patients with uncomplicated duodenal ulcer had one of four operations: selective vagotomy without pyloroplasty (S.V.) or with pyloroplasty (S.V.+P.), or proximal gastric vagotomy without pyloroplasty (P.G.V.) or with pyloroplasty (P.G.V.+P.). It has been claimed that 'dumping' may be prevented by S.V. and by P.G.V. (Amdrup and Jensen, 1970).

Gastric food residue was measured after a 12-hour fast before operation and 3 months afterwards. The gastric emptying pattern of a hypertonic dextrose 'meal' was assessed by a dye-dilution technique. The occurrence of 'dumping' was noted.

All patients had a uniform gastric-emptying pattern before operation. After all operations more rapid initial gastric emptying occurred; the difference was highly significant after S.V.+P. and P.G.V.+P. Final gastric emptying was significantly shorter after P.G.V.+P. and was significantly longer after S.V.

Eight patients developed 'dumping', 7 of whom had pyloroplasties. Significantly more rapid initial gastric emptying occurred in patients with 'dumping'. Gastric food residue only occurred after S.V.

P.G.V. retains the most normal emptying pattern. S.V. leads to gastric retention. Pyloroplasty increases the gastric emptying rate. 'Dumping' is associated with rapid initial emptying and with pyloroplasty.

Amdrup, E., and Jensen, H. E. (1970), *Gastroenterology*, **59**, 522.

27. A Radio-isotope Method of Measuring Gastric Emptying, Reflux, and Secretion: R. A. Hinder, C. G. Bremner, and B. K. P. Horn (D. J. Du Plessis), Department of Surgery, University of the Witwatersrand, Johannesburg.

Existing methods of measurement of gastric emptying do not allow for the measurement of volume added by gastric secretion, duodenal reflux, or swallowed saliva, and thus do not accurately measure the total pyloric outflow.

A radio-isotope method of measurement of intragastric volumes has been devised by using the Volemetron, an apparatus usually used for the measurement of blood-volumes. A measured dose of RIHSA^{125} is introduced into the stomach, and the dilution factor of this dose allows for the estimation of intragastric volumes by the Volemetron. The test is carried out at 20-minute intervals following a milk or water meal. The method has been cross-checked with a dilutional dye technique (George, 1968) and found to be accurate.

Using a Packard gamma counter, the radioactivity of samples of gastric content is measured each time the intragastric volume is calculated.

These results are used in the following formulae to calculate the volume of fluid added to the original meal (A) and the total pyloric outflow (B) for each 20-minute period:—

$$A = -(V_1 - V_0)\frac{\log_e(C_1/C_0)}{\log_e(V_1/V_0)},$$
$$B = A - (V_1 - V_0),$$

where V_0 is the initial volume in the stomach; V_1, the final volume in the stomach; C_0, the initial concentration of isotope; and C_1, the final concentration of isotope.

In a group of 6 dogs, following a milk meal of 20 ml. per kg. body-weight (mean 307 ml.) the mean results per hour were as shown in the table.

	A (ml.)	B (ml.)	B AS PERCENTAGE OF ORIGINAL MEAL
Normal	75	207	73
After 3–5-cm. pyloroplasty	87	240	74

The increased volume of fluid added per hour in the post-pyloroplasty dogs is probably a reflection of marked duodenal reflux.

George, J. D. (1968), *Gut*, **9**, 237.

28. Liver Metastases—A Clinical Study: R. M. Grant and W. H. H. Garvie (J. N. Norman), Department of Surgery, University of Aberdeen, Scotland.

Studies in the rat (Garvie and Grant, 1971) have suggested that a carcinoma growing at a site remote from the liver can cause changes in hepatic glycogen metabolism. In order to determine whether this also occurs in man three groups of 9 patients were studied. The groups, which were of similar age and sex, consisted of (1) controls, (2) patients with colonic neoplasm and liver metastases, (3) patients with colonic neoplasm who had no evidence of hepatic metastases at laparotomy.

Fasting blood-sugar was estimated and 25 g. glucose given intravenously. Blood-sugar estimation was made

60 minutes later and then glucagon (0·01 mg. per kg. body-weight) was given intravenously. Further estimations of blood-sugar were made 10, 20, and 30 minutes later.

Fasting blood-sugar was similar in all groups. In the control group blood-sugar had returned to normal by the end of the first hour but it rose rapidly following glucagon. The group with hepatic metastases still had an elevated blood-sugar level at the end of the first hour and glucagon made little difference. The responses of the neoplastic group without evidence of hepatic metastases fell midway between the other two groups.

Glycogen metabolism in the liver is thus grossly affected by the presence of hepatic metastases. Even where there is no evidence of metastases the primary neoplasm itself appears to be able to influence the ability of the liver to metabolize carbohydrates.

Garvie, W. H. H., and Grant, R. M. (1971), *Br. J. Cancer*, **25**, 166.

29. Steroidogenesis in Human and Rat Mammary Adenocarcinoma: W. Miller, T. Hamilton, and A. P. M. Forrest, Department of Clinical Surgery, Edinburgh.

Human breast cancer tissue has been shown to act as a para-endocrine organ by virtue of its ability to transform steroids into physiologically active hormones (Jones et al., 1970). Mammary tumours induced in the Sprague-Dawley rat by dimethylbenzanthracene (DMBA) have also been used as an experimental model for human tumours (Huggins et al., 1961).

A direct comparison of the steroidogenic capabilities of the human breast cancer with the rat DMBA-induced adenocarcinoma has been made.

In vitro slices of two rat adenocarcinomata and two human breast cancers were incubated *in vitro* with dehydroepiandrosterone (DHA) ^{3}H and testosterone ^{14}C. The conversion of DHA to testosterone and of testosterone to 5-dihydrotestosterone and 16-hydroxytestosterone were determined by measuring the percentage incorporation of the appropriate radioactive label into the thin-layer chromatography.

The pattern of steroid metabolism was identical for both human and rat adenocarcinomata but the level of steroid conversion was greater in the rat tumours. This similarity is further evidence of the value of the DMBA tumour as an experimental model for human breast cancer.

30. Antibody Production in Breast Cancer: M. Maureen Roberts, Eleanor M. Bass, and I. W. J. Wallace (A. P. M. Forrest), Department of Clinical Surgery, Edinburgh.

Tissue extracts have been prepared from 14 benign and 35 malignant breast tumours. Normal breast tissue was available from 16 cancer patients. The total protein concentration (Lowry et al., 1951) and the immunoglobulins (Mancini et al., 1965) IgA, IgG, and IgM were estimated in all tissues and sera.

We have found a significant decrease in mean total immunoglobulin production in cancer tissue (86·8 mg. per cent) compared with benign tissue (119·3 mg. per cent). Although IgM was detected in only one-third of extracts, the mean absolute value was higher in tumour tissues (7·8 mg. per cent) than in benign tissues (2·9 mg. per cent). In 4 of the 8 cancer patients in whom control tissue was also studied, absolute values of IgM were consistently higher in the tumour tissue. Levels of IgM and IgG, but not IgA, correlated closely with the degree of round-cell infiltration of the tumour. Levels of IgM in tumours with marked round-cell infiltration were significantly higher than in benign tissues.

In 4 of 16 cancer patients tested we have found precipitating antibodies to tumour in the serum, whereas none could be detected in the serum to the 13 benign or normal tissues studied.

31. Protective Effects of Orchidectomy on Tumour Induction and Transplantation in Mice: J. E. Castro, M.R.C., Clinical Research Centre, Northwick Park, Harrow, Middlesex.

Females of most species are immunologically more competent than males. Orchidectomy causes potentiation of immunity as evidenced by accelerated skin-allograft rejection and increased response to some antigens (Castro and Hamilton, 1971). Orchidectomy increases the total number of thymus-dependent lymphocytes (O-positive) and slightly increases macrophage activity shown by increased clearance of carbon particles.

Balb C mice aged 3 months were used. Half were orchidectomized 6 weeks previously and sham-operated animals served as controls. Subcutaneous, dorsal sarcomata (which are not obviously hormone dependent) were induced by methylcholanthrene in oil. The rate of tumour induction was significantly slower in orchidectomized mice and the total number of them developing tumour was 23/36 (64 per cent) compared with 32/36 (89 per cent) in the controls.

Orchidectomized mice were slightly but significantly protected when challenged with a single-cell suspension of a methylcholanthrene-induced leukaemia (normally maintained in an ascitic form) given intraperitoneally. However, when the tumour was injected subcutaneously as a single bolus, so that it grew in a solid form, the protective effects of orchidectomy were increased.

These experiments suggest that orchidectomy by its immunopotentiating effects may have wider application to tumour therapy than the present role of treating 'endocrine-dependent' tumour alone.

Castro, J. E., and Hamilton, D. N. H. (1971), *Br. J. Surg.*, **58**, 870.

32. Macrophage Production in Response to the Growth of an Experimental Tumour: M. Baum and B. Fisher, Department of Surgery, University of Pittsburgh, U.S.A.

Tumours evoke a host response that resembles a delayed hypersensitivity reaction. The macrophage is recognized as playing a critical role in initiating and maintaining such reactions and may control immunoglobulin-mediated enhancement by clearing antibody antigen complexes from the circulation (Haughton, 1971).

The macrophages that populate the reticulo-endothelial system probably arise from rapidly dividing precursors in the bone-marrow. A method for studying this phenomenon is now available (Bradley and Metcalf, 1966).

C3H mice implanted with a syngeneic mammary tumour were killed at intervals from 24 hours to 21 days. Marrow cells were harvested from the femurs of each mouse, mixed with a semi-solid nutrient medium and plated out with 10^5 cells in each of a replicate series of 10 plates. These were then incubated for 7 days, by which time pure colonies of macrophage were found. The colony count was taken to represent the number of plated cells actively proliferating at the time of harvest.

Within 4 days of the tumour challenge there was a significant increase in macrophage production, but this response became exhausted after 2 weeks of progressive tumour growth. No such changes occurred in control mice implanted with kidney tissue.

These experiments suggest the presence of an as yet unexplored phenomenon relating to the host's response to a tumour.

HAUGHTON, G. (1971), *Cell Immunol.*, **2**, 567.

33. Serum-mediated Impairment of Lymphocyte PHA Responsiveness by Gut Cancer:

A. J. EDWARDS, G. F. ROWLAND, MARGARET R. SUMNER, and C. M. HURD, St. Bartholomew's Hospital, London.

Whittaker and Clark (1971) showed depression of PHA-induced lymphocyte transformation in early breast cancer and, on the grounds that the effect was abolished on culture in control serum, claimed the presence of a depressant serum factor produced by malignancy. Al-Sarraf and Vaitkevicius (1971) dismissed this as a non-specific homologous effect.

PHA transformation was measured in 6 patients with gastro-intestinal cancer and in 6 patients undergoing laparotomy for other reasons. To test the possibility that a depressant factor is produced by the tumour and released into the circulation, each patient's lymphocytes were cultured in autologous peripheral or portal blood serum. In the cancer group the mean transformation index of peripheral lymphocytes in peripheral serum was 52·4 while these cells in portal serum gave 35·9. Each cancer patient showed an inhibition, the mean being 35·5 per cent ±9·5 (S.E.). No inhibition was observed in the control group, the mean indices being 19·5 and 18·7. Mean indices of portal lymphocytes from cancer patients were 41·6 in portal and 44·1 in peripheral serum, and in control patients they were 18·1 and 24·7.

It is concluded that tumour-effluent blood contains a factor inhibitory to lymphocyte transformation which becomes attached to the draining lymphocytes.

34. The Relationship between Pyloric Reflux and Gastric Ulcer:

R. C. G. RUSSELL, R. G. FIDDIAN-GREEN, M. A. HASSAN, C. M. S. ROYSTON, and M. HOBSLEY, Department of Surgical Studies, The Middlesex Hospital, London.

Pyloric reflux has been incriminated in the aetiology of gastric ulceration. To test this hypothesis, reflux has been determined indirectly by the use of mathematically derived formulae. Sixty-three subjects (20 control subjects, 20 duodenal ulcer patients, and 23 gastric ulcer patients) underwent a maximal histamine infusion test. When a plateau response had been obtained three 15-minute samples of gastric juice were collected. The average volume, the average sodium ion output, and the average hydrogen ion output were calculated. The average reflux for the three groups was control group 1·15 ml., duodenal ulcer patients 2·33 ml., and gastric ulcer patients 5·18 ml. There was significant difference between the gastric ulcer and the control groups, but not between the duodenal ulcer and control groups.

In gastric ulcer patients a positive correlation was found between reflux and the length of history ($P < 0{\cdot}001$), and the regression equation indicated that at zero length of history there was minimal reflux.

Whether the reflux is a cause or an effect of the gastric ulcer will depend on the relationship between the onset of symptoms and the appearance of the ulcer.

35. Patterns of Gastric Secretory Response to an Insulin Infusion in Vagotomized Patients:

R. R. DOZOIS, D. C. CARTER, and J. R. KIRKPATRICK, Department of Clinical Surgery, Edinburgh.

A 3-hour insulin infusion produces a steady state of acid secretion in response to a steady level of hypoglycaemia in healthy volunteers (Carter et al., 1972).

The insulin infusion test was performed in 38 vagotomized subjects. Three types of response were seen: (1) a sustained rise of at least 20 mEq./l. over basal values within 90 minutes of the start of infusion ('early positive response'); (2) a similar response occurring in the latter half of the test ('late positive response'); and (3) no significant elevation over basal values ('negative response').

The PAO_I (Baron, 1963) of subjects with an 'early positive response' (11 subjects, mean 10·6 mEq./hr. ± S.D. 8·2) and a 'late positive response' (9 subjects, mean 6·6 mEq./hr. ± S.D. 4·3) did not differ significantly ($P > 0{\cdot}05$), but these means both differed from that of the 'negative response' group (18 subjects, mean 0·66 mEq./hr. ± S.D. 1·0; $P < 0{\cdot}001$).

When the conventional insulin test and the insulin infusion test were performed in the same subjects, the timing of the response to both tests was almost identical. A close correlation between the PAO_I of each test was obtained ($r = 0{\cdot}89$; $P < 0{\cdot}001$).

36. The Effect of Fat in the Duodenum on Gastric Secretion before and after Truncal Vagotomy (T.V.) and Highly Selective Vagotomy (H.S.V.) in Man:

P. J. LYNDON and D. JOHNSTON, University Department of Surgery, General Infirmary, Leeds.

It has been suggested that mechanisms responsible for inhibiting gastric secretion are preserved after H.S.V., but sacrificed in T.V. Inhibition of gastric secretion by fat in the intestine has been reported to be unchanged (Ward, 1972) or absent (Johnston and Duthie, 1969) after T.V. in man.

Fat-induced inhibition was studied in three groups of men: (1) 8 with duodenal ulcer (D.U.) before operation; (2) 8 after T.V. + pyloroplasty (parietal cell mass denervated, small intestine denervated); (3) 8 after H.S.V. (parietal cell mass denervated, small intestine innervated). Tests were performed more than 1 year after vagotomy, which was complete on insulin testing in each patient.

A low-dose pentagastrin infusion (0·20 µg./kg./hr.) provided the stimulus, and 60 ml. of olive oil were infused slowly into the duodenum after a plateau of gastric acid output had become established. The fat elicited the following decreases in acid output (mean ± 1 S.E.M.): (1) 5·3 ± 0·8 mEq./10 min. (76 per cent) in D.U.s. (2) 0·90 ± 0·2 mEq./10 min. (37 per cent) after T.V. + pyloroplasty. (3) 1·2 ± 0·3 mEq./10 min. (44 per cent) after H.S.V.

Fat produced significant inhibition ($P < 0{\cdot}02$) in all three groups, but inhibition was impaired after either type of vagotomy, compared with before operation. Inhibition was no greater in men whose intestine was innervated (H.S.V.) than in men whose intestine was vagally denervated (T.V.).

JOHNSTON, D., and DUTHIE, H. L. (1969), *Scand. J. Gastroent.*, **4**, 561.

37. Effect of Truncal Vagotomy (T.V.), Selective Vagotomy (S.V.) and Pyloroplasty, and Highly Selective Vagotomy (H.S.V.) without Drainage on the Response to Meat Extract in Man: C. S. Humphrey, R. B. Smith, P. J. Lyndon, and D. Johnston, University Department of Surgery, General Infirmary, Leeds.

Surgery for duodenal ulcer since 1943 has been based on the concept that vagal denervation of the antrum is essential (Nyhus et al., 1960). This was thought to diminish gastrin release, so providing protection against recurrent ulceration. An excellent stimulus to gastrin release in man is meat extract (Oxo solution) It has been shown previously that the acid response to Oxo is not greater after H.S.V. without drainage (antrum innervated) than after S.V. without drainage (antrum denervated) (Johnston et al., 1971).

Patients with duodenal ulcer (D.U.) were studied (1) before operation ($n = 26$) and more than 1 year after; (2) T.V.+ pyloroplasty (18); (3) S.V.+pyloroplasty (10); and (4) H.S.V. (25). Postoperative patients were in good health and insulin-negative. The mean peak acid output (± 1 S.E.M.) in mEq./hr. in response to the test meal were (1) D.U., 21·7 ± 2·2; (2) T.V.+pyloroplasty, 16·2 ± 3·0; (3) S.V.+pyloroplasty, 11·0 ± 2·9; and (4) H.S.V., 10·1 ± 1·5.

These results indicate that vagal denervation of the gastric antrum in man fails to diminish gastrin release n response to the chemical stimulus of a test meal. Indeed, acid outputs were considerably higher after T.V.+ pyloroplasty than after H.S.V. though the difference was not statistically significant. These results are in accord with recent studies in man of plasma-gastrin levels after vagotomy.

38. Graded Vagotomy and Gastric Secretion in the Dog: S. Nundy and J. H. Baron, Department of Surgery, Royal Postgraduate Medical School, Hammersmith Hospital, London.

The current vagal operations for peptic ulcer, truncal vagotomy (T.V.), selective vagotomy (S.V.), and highly selective vagotomy (H.S.V.) all aim at complete denervation of the acid-producing area of the stomach, the assumption being that incomplete vagotomy does not alter acid production. We have tried: (1) to establish whether the stomach does respond in an 'all-or-none' fashion to vagal stimulation; (2) to compare the vagally (insulin) and chemically (pentagastrin) stimulatable secretion after graded division of the vagus nerve performed successively in the same animal.

The acid and pepsin responses to increasing doses of insulin and pentagastrin were measured in 3 dogs with chronic gastric fistulae after operations performed in the following sequence: (1) 'Half a highly selective vagotomy' (H.H.S.V.), dividing the nerves from the antral border to 1 cm. from the oesophagogastric junction; (2) H.S.V., dividing nerves in the remaining lesser omentum and around the lower oesophagus; (3) S.V., dividing the antral nerve; (4) Trans-thoracic truncal vagotomy.

Results.

1. *Insulin*: Peak outputs (per cent of control output ± S.E.M) were as shown in the table.

	Control (per cent)	H.H.S.V.	H.S.V.	S.V.	T.V.
Acid	100	45 ± 6	4 ± 1	4 ± 2	8 ± 4
Pepsin	100	30 ± 3	4 ± 1	3 ± 1	2 ± 1

2. *Pentagastrin*: Submaximal doses resulted in a lower acid output but the maximal response was unchanged.

The gastric secretory response after vagotomy is not an all-or-none phenomenon but is related to the extent of denervation of the acid-producing area.

After a highly selective vagotomy no further changes in secretory output to stimulation occurred when selective and truncal vagotomy were performed successively in the same animal.

39. Relationships between Acid Output to Pentagastrin, Gastric Pepsin Output to Insulin, and Lean Body Mass: J. B. Elder and I. S. Smith, University Department of Surgery, Manchester Royal Infirmary, and Gastrointestinal Centre, Southern General Hospital, Glasgow.

Gastric acid output has been related to parietal cell mass (Card and Marks, 1960) and to lean body mass (Hume and Melrose, 1967). Little is known of the relationship of pepsin output to gastric acid output and to lean body mass.

In assaying pepsin we found that insulin-stimulated peak pepsin output (mg. per 30 min.) correlated well with pentagastrin-stimulated peak acid output (mEq./30 min.) in 13 normal subjects ($r = 0{\cdot}89$, $P < 0{\cdot}001$).

Lean body mass was calculated and pepsin output to insulin was found to show good correlation with lean body mass ($n = 13$, $r = 0{\cdot}67$. $P < 0{\cdot}02$). It appears likely that peak pepsin output after insulin reflects peptic cell mass in normal subjects.

In 28 duodenal ulcer subjects there was no obvious correlation of individual acid and pepsin outputs with lean body mass. However, alternative analysis suggests the existence of separate subgroups. Mean peak pepsin output per kg. lean body mass for the ulcer subjects was significantly greater than normal ($P < 0{\cdot}001$), suggesting an increased number of peptic cells or alternatively increased sensitivity to insulin stimulation.

40. Gastric Secretory Reduction after Vagotomy with an Innervated Antrum: R. J. Clarke, R. N. Allan, and J. Alexander Williams, The General Hospital, Birmingham.

A prospective randomized trial was conducted to show whether preservation of antral innervation by proximal gastric vagotomy (P.G.V.) produces adequate reductions of gastric secretion. Forty male duodenal ulcer patients had either a P.G.V. or a selective vagotomy (S.V.).

A combined insulin/pentagastrin test was used to assess gastric secretion (Baron et al., 1969). Estimations were made of the basal output of acid (B.A.O.) and pepsin (B.P.O.), the post-insulin maximal output of acid (M.A.O.$_{\text{I}}$) and pepsin (M.P.O.$_{\text{I}}$), and the post-pentagastrin peak output of acid (P.A.O.$_{\text{pg}}$) and pepsin (P.P.O.$_{\text{pg}}$).

The postoperative reductions of gastric secretion for P.G.V. and S.V. respectively were: B.A.O., 74 and 80 per cent; B.P.O., 75 and 50 per cent; M.A.O.$_{\text{I}}$, 96 and 92 per cent; M.P.O.$_{\text{I}}$, 94 and 87 per cent; P.A.O.$_{\text{pg}}$ 70 and 61 per cent; and P.P.O.$_{\text{pg}}$, 69 and 56 per cent.

There were no significant differences in gastric secretion before or after operation when P.G.V. was compared with S.T.V. Seven patients had a positive-acid response to insulin by the criteria of Hollander, 5 had S.V. and 2 had P.G.V.

Preservation of antral innervation is compatible with complete vagal denervation of the acid-and pepsin-secreting cells of the stomach.

41. Studies of Gastric Acid Secretion after Small-bowel Resection:

J. H. Saunders, B. Buxton, and B. S. Bedi, University Department of Surgery, Western Infirmary, Glasgow.

Recent studies have shown that extensive small-bowel resection results in increased gastric acid secretion in dogs with denervated gastric pouches. The effect of small-bowel resection on acid secretion in dogs with innervated pouches was studied and the effect of antrectomy on gastric secretion defined.

Four dogs were prepared with vagally innervated pouches (group I). In another 4 animals an antrectomy was also performed at the time of pouch construction (group II). The adequacy of antrectomy was confirmed by histology. Both groups subsequently underwent a 75 per cent small-bowel resection.

Twenty observations of daily acid output in response to a standard meal were made before and after small-bowel resection.

The daily acid output in group I rose from 16·24 ± 0·68 mEq. before resection to 22·97 ± 1·23 mEq. after resection.

There was no increase in acid output following resection in group II. The results suggest that small-bowel resection in dogs results in an increased acid output from vagally innervated gastric pouches and that this can be prevented by antrectomy.

42. Radio-isotopic Investigation of Protein Synthesis and Reticulo-endothelial Activity following Partial Hepatectomy in the Rat:

S. J. Karran, K. G. Leach, and L. H. Blumgart, Departments of Surgery and Medical Physics, Welsh National School of Medicine and University Hospital of Wales, Cardiff Royal Infirmary.

Radio-isotopic scanning of the rat liver allows observation of the concentration of substances by different cellular systems within the liver both before and after partial hepatectomy (Croft, 1969; Karran et al., 1972). This paper reports quantitative investigation of the uptake and distribution of ^{75}Se-seleneomethionine (SM) and ^{99m}technetium-sulphur-colloid (TSC) to assess protein synthesis and reticulo-endothelial activity.

One hundred and twenty male Sprague-Dawley rats weighing 230–450 g. were studied using ether anaesthesia.

Uptake of the labelled amino-acid increased soon after partial hepatectomy, reaching a maximum at 6 hours and returning to near normal values by 3 days (80 animals). This increase was independent of the dosage below loading levels. Activity incorporated into liver protein was markedly raised at 12 hours ($P < 0{\cdot}001$).

Uptake of the colloid per g. reached a maximum immediately after partial hepatectomy, whereas total uptake decreased slightly. Normal levels were regained by 5 days (40 animals). The uptake of both compounds by each lobe of the liver was within ± 5 per cent of the mean value both before and after partial hepatectomy.

These results show that protein synthesis increases very soon after hepatic resection and suggest that there is an immediate increase in blood-supply to the remnant as shown by the uptake of the colloid.

43. Ovarian Implantation into the Spleen of Normal and Portacavally Shunted Rats:

Susan E. Seager, L. H. Blungart, and A. R. Boyns, University Departments of Surgery and Chemical Pathology, Welsh National School of Medicine and the Tenovus Institute of Cancer Research, Cardiff.

The original suggestion (Zondek, 1934) that oestrogens are inactivated by the liver was followed by investigations into changes in ovarian implants into the spleen of spayed rats. Granulosa-cell tumours and luteomas have been reported. Failure of such implants to undergo hyperplasia has been attributed to the presence of adhesions between the spleen and parietal peritoneum (Biskind and Biskind, 1949).

This paper reports an investigation of ovarian implants into the spleen of normal and rats with portacaval shunts.

Follicular development with luteinization was demonstrated in spayed rats after implantation and after 175 days masses of compressed corpora lutea were seen. Twenty animals with portacaval shunts, performed at the same time as implantation, showed markedly less luteal development but moderate follicular growth. Regression of hyperplasia was seen at 175 days after implantation, when portacaval shunts were performed in animals with hyperplastic implants. Hyperplasia only occurred when the implant effluent was allowed to pass through the liver.

No abnormal cells were seen in the implants at any stage.

Ovarian implants into the spleen offer a preparation for the study of ovarian–pituitary relationships.

44. Mucous Change in the Duodenum:

W. J. A. Patrick and D. Denham (A. P. M. Forrest), Department of Clinical Surgery, University of Edinburgh.

In 1935 Florey and Harding described the healing of artificial defects in the duodenal mucosa of cats by mucus-containing epithelium which they believed originated in Brunner's glands. Clumps of mucous cells have been described on the villi of the duodenal mucosa in the majority of patients with chronic duodenal ulceration and in a minority with chronic gastric ulcers or gastric cancer.

We have re-examined the significance of mucous change in the duodenum in upper gastro-intestinal disease in 62 patients with duodenal ulcers, gastric ulcers, or gastric cancer. Duodenal biopsies were obtained at operation and histological sections stained with periodic acid-Schiff reagent (PAS) for mucus.

The incidence of mucous change is high in patients with peptic ulcer disease, particularly of the duodenum. Contrary to what Rhodes (1964) suggested, there is no relationship between mucous change in the duodenum and the maximal acid output of the stomach.

The fine structure of the mucous cells in man has been examined with the electron microscope and the cells have been seen to arise from progenitor cells in the crypts.

45. The Effect of Insulin on Canine Bile-secretion and Composition:

A. C. MacDonald, R. A. MacAllister, and C. MacKay, University Department of Surgery, Western Infirmary, Glasgow.

Gall-stone disease is associated with alterations in the lipid composition of bile (Admirand and Small, 1968), and is said to occur more commonly in vagotomized patients (Fletcher and Clark, 1968). It is important, therefore, to study the action of the vagus on bile-secretion.

We have studied the effect of insulin and atropine, separately and in combination, on bile-volume, bile-lipid (bile-salts, phospholipid, and cholesterol) secretion, and acid output on two occasions in 6 healthy dogs prepared with chronic biliary and gastric fistulae.

The maximum drug effects usually occurred in the second hour after injection. Insulin (1 unit per kg.) produced a significant increase in bile-volume (23·8 ± 2·2 to 47·6 ± 4·9 ml. per hr.) and bile-salt output (1·5 ± 0·2 to 2·2 ± 0·3 mmol. per hr.). Atropine (0·08 mg. per kg.) failed to block the choleretic action of insulin although it almost abolished its stimulatory action on acid secretion. This suggests that the choleretic action of insulin is mediated via non-vagal mechanisms. Atropine (0·08 mg. per kg.) itself caused a significant reduction in bile-volume (26·3 ± 2·6 to 16·8 ± 1·6 ml. per hr.) and in the secretion of bile-lipids, suggesting that there is a vagal component responsible for basal bile-secretion.

46. **Prophylactic Synovectomy is Therapeutic:** R. A. DICKSON and F. V. NICOLLE, Royal Postgraduate Medical School, London.

Synovectomy of the metacarpophalangeal joints of the hand may relieve pain and prevent the development of erosions. New information about hand function following synovectomy has been discovered using two new techniques of assessment—that of the measurement of individual digital forces (Dickson and Calnan, 1972), and that of the measurement of the density of the bones of the individual digits of the hand (Dickson et al., 1972).

The forces and bone densities of the hand were measured before and after prophylactic synovectomy of the metacarpophalangeal joints in 10 patients. The forces of the digits operated upon increased by approximately 100 per cent following surgery, while the forces of the remaining digits increased by about 10 per cent, presumably due to the increase in overall hand function resulting from surgery. Bone density increased in precisely the same manner following synovectomy.

Synovectomy leads to functional improvement in the hand and can reverse the general trend of osteoporosis. Prophylactic synovectomy therefore merits the prefix therapeutic.

47. **A Three-phase Gas Exchanger for Blood Perfusion of Isolated Organs:** A. ZONTA, R. DIONIGI, L. DOMINIONI, and P. DIONIGI, Istituto di Semeiotica Chirurgica Laboratori di Chirurgia Sperimentale, Università di Pavia, Italy.

The results obtained with a gas exchanger designed for blood perfusion and based on a new principle of interposition of a phase of O_2-saturated water between blood and gas are presented. Oxygen uptake and CO_2 removal take place between blood and water separated by a silicone-rubber membrane.

Respiratory efficiency was tested determining: transfer of O_2 to blood and CO_2 removal at constant flow rate, with oxymetric determination of content; inlet and outlet Po_2 and Pco_2; and blood acid-base balance according to the Astrup method.

Plasma-protein degradation and R.B.C. damage were studied in recirculated blood for periods of 2–24 hours, determining: total and plasma Hb, plasma LDH, blood lactate, erythrocyte osmotic fragility, R.B.C. and W.B.C. and platelet counts, specific viscosity, and protein fraction β-lipoproteins.

The unit demonstrated a capability of saturating whole blood with a haematocrit of 40 from normal venous O_2 content to saturation at flow rates up to 100 ml. per min.

CO_2 elimination is slightly higher, requiring, for long-term perfusions, saturation of water with O_2–CO_2 mixtures. The low hydrosolubility of O_2 required high deliveries in water circuits (1000–1300 ml. per min.).

Plasma-protein degradation appears low. Significant viscosity changes and consistent lipoprotein alteration did not develop. The haemolysis is rather constant during the experimental period, resulting in an average plasma haemoglobin production of 0·76 mg. per m.^{2} per min.

48. **Peripheral Lymphatic Pressures in Normal Subjects:** R. D. QUILL and P. BYRNE (W. G. Fegan), Clinical Research Department, Sir Patrick Dun's Hospital, Dublin.

Pressures in lymphatic vessels on the front of the ankle in normal subjects have been measured on a tilt table.

The Pressures:—

In the horizontal position, at rest (6 subjects), ranged from 2 to 5 mm. Hg (mean 4·1).

During or immediately after plantar flexion of the ankle against resistance (5 subjects) there was a rise to between 5 and 12 mm. Hg (mean 7·8).

After tilting to between 45° and 75° (5 subjects), the mean pressures were: resting, 4·1 mm. Hg; during or immediately following plantar flexion of the ankle, 6 mm. Hg.

In 5 subjects spontaneous rises in pressure (by up to 3 mm. Hg) at intervals of 0·5 minute were observed. These were thought to be artefacts due to obstruction of the lymphatic by the proximally pointing recording needle, resulting in a slow build-up pressure below the needle, and a transient recorded pressure rise as lymph by-passed the obstruction. In 1 subject, however, a distally pointing needle was introduced and transient sharp rises in pressure were observed.

It appears that, unlike the venous system, there is no significant hydrostatic component in peripheral lymphatic pressures.

49. **Lung Scans using ^{131}I Human Plasminogen:** J. J. SPINDLER, V. V. KAKKAR, and M. SCULLY (C. T. Howe), Department of Surgery, King's College Hospital Medical School, London.

Abnormal lung scans using ^{99m}TcMAA are not specific for pulmonary embolism. Pneumonic consolidation, pleural effusion, and carcinoma will show as perfusion defects. An attempt was made to label pulmonary emboli with ^{131}I human plasminogen. It was hoped that the fibrin in the emboli would take up the radioactive plasminogen and an area of increased radioactivity would be seen on the lung-scan film.

An experimental model was set up. Venous thrombi were induced in greyhounds by a venotomy and scarifying the endothelium. Forty-eight hours later these thrombi were injected into the venous system and pulmonary emboli were thus established. Laboratory prepared and commercial plasminogen was labelled by one of three different techniques. The iodine monochloride iodination of MacFarlane was preferred. ^{131}I human plasminogen (500 ci) was injected i.v. and the lungs scanned with the gamma camera for about 10 hours.

Lung scans showed areas of increased radioactivity and pulmonary angiograms confirmed the presence of emboli. These pulmonary emboli were removed from the heparinized dog and the radioactivity was measured and compared with the radioactivity in the sample of blood. The concentration of ^{131}I plasminogen in the clot was 3–7·5 times that in the blood, showing an uptake of ^{131}I bovine albumin.

50. **Small-bowel Flora and Bowel Habit studied at Intervals following Vagotomy and Drainage:** G. G. BROWNING, K. A. BUCHAN, and C. MACKAY, Department of Surgery, Western Infirmary, Glasgow.

Post-vagotomy diarrhoea may be related to bacterial colonization of the upper small intestine. Eighty per cent of the patients have significant colonization of the upper small intestine in the first 7–10 days following truncal vagotomy and drainage (MacKay et al., 1969).

Twenty-five patients who had been studied in the immediate postoperative period were reassessed as regards their small-bowel flora and bowel habit on average 18 months (range 6–28) following surgery. Fourteen of these patients had a gastro-enterostomy and 11 a pyloroplasty. The incidence of significant colonization following gastro-enterostomy fell from 86 per cent (12 of 14) to 50 per cent (7 of 14), while the significant incidence of colonization following pyloroplasty fell from 100 per cent to 9 per cent (1 of 11). The difference between the two drainage procedures at follow-up is statistically significant ($P < 0{\cdot}05$). Of the 25 patients studied, only 2, both with a gastro-enterostomy, subsequently developed diarrhoea. Of these only 1 had a significant colonization of the upper small bowel.

The initial high incidence of colonization in pyloroplasty patients is not maintained.

In gastro-enterostomy patients, although there is a fall in incidence, 50 per cent of the patients are still significantly colonized on follow-up.

Owing to the low incidence of diarrhoea no aetiological connexion can be made between this symptom and colonization of the upper small bowel.

MacKay, C., Browning, G. G., and Buchan, K. A. (1969), *Br. J. Surg.*, **56**, 706.

51. The Effect of Potassium Loading on the Intestinal Handling of Electrolytes: Anne Hardy-Smith, Alma Birch, and R. Shields, Department of Surgery, University of Liverpool.

Controversy still exists concerning the effect of adrenal mineralocorticoids upon the intestinal handling of electrolytes. In most studies aldosterone has been administered or its secretion stimulated by inducing salt depletion. The effect of another stimulus of aldosterone secretion, potassium overloading, upon intestinal absorption of electrolytes was studied.

Thiry-Vella loops of ileum and colon were fashioned in 4 dogs and their ability to absorb water and electrolytes determined by established methods, following the intravenous load of 15 mEq. KCl, with and without dietary loading of 240 mEq. KCl and 120 mEq. NaCl. Changes in body electrolytes and extent of potassium overloading were monitored by measuring plasma, urinary and red blood-cell electrolytes, as well as total exchangeable sodium and potassium.

Acute intravenous loading produced increases of 2·1–4·2 mEq. K^+/l. plasma within 1 hour, with return to normal 6 hours later. Chronic dietary loading did not affect the plasma-potassium concentration despite profound E.C.G. changes.

Net intestinal transport of potassium was decreased largely as a result of increase flux of potassium from blood to lumen.

These results further define the action of mineralocorticoids upon the intestine and suggest that a protective mechanism may exist to reduce potassium transport from the gut when the body is being overloaded with potassium.

52. The Role of Peritoneal Lavage in Acute Intestinal Ischaemia: D. T. Caridis, Department of Surgery, University of Aberdeen, Scotland.

The usefulness of peritoneal lavage as a therapy for acute ischaemic injury of the gut was investigated on rabbits subjected to 1-hour transient occlusion of the superior mesenteric artery. The untreated controls ($n = 6$) died within 2 hours of release of the occlusion with a mean plasma volume loss of 30 per cent and endotoxaemia (mean 1·0 µg. per ml.). Intermittent lavage for 6 hours prevented endotoxaemia during the period of lavage, reduced plasma loss by 50 per cent, and prolonged survival of this group ($n = 10$) by 24 hours. In a further group ($n = 10$) replacement of plasma deficit did not improve the results from lavage alone. The gain from adding intra-intestinal kanamycin into the bowel after release of the occlusion was, however, considerable, for half of this group ($n = 10$) survived for 48 hours and the remainder had complete recovery. The amount of endotoxin recovered from peritoneal lavage fluid averaged 72·6 µg. per animal. The data demonstrate that this therapy by eliminating endotoxaemia can achieve survival from an otherwise uniformly lethal disorder.

53. Lymphocyte Transformation in the Mesenteric Lymph-nodes of Patients with Crohn's Disease: P. J. Guillou, G. R. Giles, and T. G. Brennan, University Department of Surgery, St. James's Hospital, Leeds.

The circulating lymphocytes of patients with Crohn's disease have a diminished transformation rate to phytohaemagglutinin (PHA) (Walker and Greaves, 1969). Six patients with ileocaecal Crohn's disease and 6 patients with non-inflammatory gastro-intestinal conditions were studied and the lymphocyte transformation rate (L.T.R.) to PHA compared in the peripheral blood and in mesenteric lymph-nodes.

The L.T.R. of blood lymphocytes in control subjects averaged 46·6 per cent (S.E. ± 1·7 per cent) compared with a mean of 35·8 per cent (S.E. ± 3·6 per cent) in patients with Crohn's disease ($P = 0{\cdot}01$). Similarly the mean L.T.R. of lymph-node lymphocytes was 41·1 per cent (S.E. ± 3·9 per cent) in the control subjects and 21·9 per cent (S.E. ± 3·6 per cent) in the patients with Crohn's disease ($P = 0{\cdot}002$). Cells obtained from lymph-nodes directly draining diseased bowel had the lowest L.T.R. (17·6 per cent S.E. ± 4·4 per cent) compared with cells in the nodes situated centrally at the root of the mesentery (28·8 per cent S.E. ± 4·8 per cent). In control subjects no such gradient existed. The diminished L.T.R. to PHA in patients with Crohn's disease was not increased by culture in pooled homologous AB serum. Likewise lymphocytes from control patients did not show reduced L.T.R.s when incubated in the serum of patients suffering from Crohn's disease.

These findings suggest that in patients with Crohn's disease the reduced L.T.R. in blood is the result of some local action at the site of disease.

54. Diverticular Disease treated by Methyl Cellulose Tablets: W. J. B. Hodgson (B. N. Brooke), Surgical Unit, St. George's Hospital Medical School, London.

Following animal experiments previously reported to the Society, 6 patients with diverticular disease were seen and examined and their rectosigmoid pressures were measured, using two fluid-filled open-tipped narrow-bore polythene tubes placed at 20 and 10 cm. from the anal margin through a sigmoidoscope. Pressures were measured for a resting period of 30 minutes, during feeding, and during a post-prandial period of 30 minutes. Results were expressed quantitatively using the colonic motility index (Chaudhury and Truelove, 1961). Activity was eight to ten times greater at the rectosigmoid than in the rectum.

The patients received a 6-month course of methyl cellulose (Celevac) tablets. No attempt was made to change their habitual low-residue diet. After this they were reassessed and examination and pressure measurements repeated as before. Results before and after methyl cellulose were compared.

All patients had become symptom-free; sigmoidoscopy had become technically much easier and activity at the rectosigmoid had fallen significantly to rectal levels, which remained the same. Since rectal pressures increase after colonic resection for diverticular disease (Parks, 1970) the bulk-forming action of methyl cellulose would appear to be rational and effective treatment and suggests that the acquired condition of diverticular disease is reversible.

55. The Effects of Dietary Supplements of Wheat Bran and Cellulose upon Bowel Function:

T. HAMILTON, J. R. KIRKPATRICK, D. MITCHELL, and M. A. EASTWOOD, Departments of Clinical Surgery and Medicine, Edinburgh.

It has been suggested that diseases of the colon in Western society are related to a reduction in dietary 'fibre'; and high-residue diets have been advocated in the treatment of diverticular disease of the colon (Painter and Burkitt, 1971).

The effects of wheat bran and cellulose upon bowel habit and certain constituents of faeces have been investigated. Faeces were collected for 5 days from 8 healthy males before and during the ingestion of a daily dietary supplement of 16 g. unprocessed wheat bran over a 3-week period. Following a further 3-week control period the effect of a daily supplement of 16 g. cellulose was assessed in 4 of the subjects. Intestinal transit time was measured using radio-opaque markers (Hinton et al., 1971). Stools were weighed and faecal bile acids, faecal fat, and serum cholesterol measured.

Neither bran nor cellulose had a significant effect upon intestinal transit time or upon the frequency of stools. Wet weight of stool increased significantly but there was no change in total bile-acid excretion, faecal fats, or serum cholesterol. It is concluded that any therapeutic benefit from bran or cellulose results from increased water content of stool rather than from alteration in transit time.

56. Urodynamic Assessment of Bladder Dysfunction following Spinal Injury:

D. G. THOMAS, R. H. SMALLWOOD, and D. W. GRAHAM (M. Fox), Spinal Injuries Unit, Lodge Moor Hospital, Sheffield.

Fifty patients with spinal injuries have been investigated by measuring urethral pressure profiles (Brown and Wickham, 1969) and pressure/flow values with synchronous radiological studies during bladder filling and voiding.

Standard methods of synchronous pressure/flow cystography (Bates and Corney, 1971) have been adapted for use in this study, employing double-lumen, nylon transurethral catheter (external diameter 1·5 mm.), slow filling of the bladder, and studying patients in the supine/oblique position.

The parameters recorded were: total bladder pressure, rectal pressure, intrinsic bladder pressure (cm. of water), voiding volume (ml.), voiding flow rate (ml. per sec.), and an integrated EMG of the external anal sphincter.

Fifteen spinal injury patients with returning reflex bladder activity were studied between 2 weeks and 9 months after injury.

The static urethral pressure at the level of the external urethral sphincter increased gradually during the post-injury period concomitant with increasing reflex somatic activity.

The external urethral sphincter is normally physiologically silent during micturition; in the paraplegic patient during a single act of voiding there is continuous and varying external sphincter activity. This incoordination between the detrusor and sphincteric mechanisms results in low flow rates often with intermittent voiding, and contributes to incomplete bladder emptying.

57. The Effects of Early Experimental Cryptorchidism and Subsequent Orchidopexy on Maturation of the Guinea-pig Testicle:

P. M. ATKINSON (C. W. Jamieson), Surgical Unit, St. Mary's Hospital, London.

The results of orchidopexy for cryptorchidism in man are disappointing. The poor results and the underlying cause of cryptorchidism are not understood. Animal experiments have shown that intraperitoneal replacement of a mature testicle prevented spermatogenesis, and subsequent orchidopexy allowed it to recover (Wangensteen, 1927). However, the effects of orchidopexy upon immature experimentally cryptorchid testicles have not been investigated.

A group of 25, 7-day-old, guinea-pigs was made cryptorchid and a similar group was used as controls. Orchidopexy was performed at varying intervals until the post-pubertal age of 100 days. Testicular biopsies were taken at 7 days, at orchidopexy, at the post-pubertal age of 120 days, and at sacrifice in young adult life. The biopsies were studied histologically. The results indicated that early experimental cryptorchidism arrested testicular development, and later orchidopexy allowed it to continue to active spermatogenesis.

An experimental situation, which was comparable to the surgical treatment of natural cryptorchidism, has been used. This situation allowed an immature but initially normal testicle to achieve spermatogenesis after orchidopexy. This would suggest that the poor results following surgical treatment in man are due to an abnormality of the testicle itself. If this is true, the failure of descent might also be the result of that abnormality.

58. Changes in Serum Complement and the Immunoglobulins after Cardiopulmonary By-pass:

D. J. PARKER, G. CANTRELL, R. STROUD, R. KARP, and S. B. DIGERNESS, University of Alabama, Birmingham, U.S.A., and London Chest Hospital.

The relationship of organ dysfunction, particularly pulmonary dysfunction after cardiopulmonary by-pass, to changes induced in the blood remains speculative. Denaturation of plasma proteins at the gas–blood interface in oxygenators has been postulated as the cause but the biochemical pathogenesis remains unexplained.

Theoretically, activation of the complement system involving the release of anaphylatoxins and kinins causing an alteration in capillary permeability could be involved. Pruitt et al. (1972) recently showed aggregates of gamma-globulin produced in an oxygenator could combine and activate complement.

Eleven patients undergoing cardiopulmonary by-pass for aortic valve disease were studied preoperatively and serially to 8 days after surgery. Serum-complement levels reduced from preoperative values of $30{\cdot}7 \pm 5{\cdot}1$ to $18{\cdot}8 \pm 2{\cdot}7$ CH50 units per ml. at 4 hours ($P < 0{\cdot}001$) and $22{\cdot}2 \pm 4{\cdot}0$ units at 20 hours ($P < 0{\cdot}001$) after surgery. Immunoglobulins IgG and IgM also showed significant falls in the postoperative period, but IgA did not. Total protein and water content of blood estimations showed that the changes were not due to haemodilution itself.

A possible explanation is that the IgG aggregates produced during cardiopulmonary by-pass combine with complement before or after interacting with capillary membranes and lead to alterations in capillary permeability and hence organ function.

59. The Action of Autologous Lymphocytes against Colon Cells from Patients with Acute Ulcerative Colitis: *in vitro* Studies: P. S. HUNT (H. A. F. Dudley), Department of Surgery, Monash University, Melbourne, Australia.

Colon mucosal cells were obtained from operative specimens and by biopsy at sigmoidoscopy from patients with acute ulcerative colitis and controls with normal large-bowel mucosa. These cells were grown in multiple monolayer microcultures and also labelled in monodisperse suspension with chromium-51 (Perlmann and Holm, 1969). Lymphocytes were separated from blood by density-gradient centrifugation and multiple washings. The ability of lymphocytes from the same patient both to detach autologous cells in microculture and to release label from cells was quantitatively assessed. There was agreement between these two tests for lymphocyte reactivity. All patients with acute ulcerative colitis and none of the controls showed lymphocyte reactivity.

The results in patients who came to urgent colectomy differed from those who responded to steroids: the former demonstrated greater lymphocyte reactivity, which was unaffected by the addition of autologous serum; in the latter serological inhibition of lymphocyte reactivity was a uniform feature.

An additional finding in the serum of patients coming to urgent colectomy was the absence of immunofluorescent auto-antibodies to normal human colon.

These findings suggest an important role for the lymphocyte in the production of colonic damage in ulcerative colitis.

60. Antilymphocyte Serum: An Investigation into the Decay Phenomenon: MARY PONSFORD (A. G. Riddell), University Department of Surgery, Bristol Royal Infirmary, Bristol.

Repeated immunization of animals producing immunosuppressive antilymphocyte serum results in the production of less potent material (Levey and Medawar, 1966; Ponsford and Symes, 1971).

Two series of rabbit anti-mouse thymocyte sera (R.A.M.T.S.) were prepared. Series I: Five weekly immunizations were followed, after an interval of 3 months, by three further weekly immunizations. Series II: Sixteen weekly immunizations were given. Animals were bled 7 days after each immunization.

The immunosuppressive potency of each serum was assessed by its ability to prolong the survival of C57B1 skin-grafts made to CBA mice. The potency of both series of R.A.M.T.S. declined after the third immunization.

The decline in potency of series II R.A.M.T.S. was paralleled by a fall in leuco-agglutinin and opsonin titres.

The administration of series I seven-pulse R.A.M.T.S. together with the three-pulse material significantly reduced the potency of the latter. In contrast later sera of series II were without effect on the potency of earlier sera.

It is suggested that, in series I, further immunization after an interval of 3 months resulted in the development of antibodies which inhibited the action of the immunosuppressive antibodies. However, in series II continuous immunization resulted in the absorption of immunosuppressive antibodies by the injected thymocytes.

61. The Isolated Perfused Rodent Thymus as a Source of Lymphocytopoietic and Immunocompetence Promoting Factors: I. W. J. WALLACE and O. EKUEME (A. P. M. Forrest), Departments of Clinical Surgery, Royal Infirmary, Edinburgh, and Royal Infirmary, Cardiff.

Isolated perfusion *in vitro* of the rabbit and the rat thymus has been performed, and studies carried out on the ability of the perfusate to reconstitute neonatally thymectomized animals of these species in a manner comparable to the effect of thymus extracts (Goldstein and White, 1970).

The rabbit thymus was perfused with a saline-diluted rabbit medium in a closed circuit system, viability being maintained for at least 6 hours. The cell-free fraction of this perfusate administered to neonatally thymectomized rabbits enhanced significantly their susceptibility to sensitization to BSA as demonstrated by subsequent development of skin hypersensitivity. No such effect was obtained with unperfused control medium.

The rat thymus was perfused in open circuit with an acellular, protein-free, complex medium (Medium 199, Wellcome) and found to remain viable for at least 12 hours as assessed by glucose utilization. The cell-free effluent, given by repeated subcutaneous injection to 25 neonatally thymectomized rats, was found to raise the peripheral blood-lymphocyte count from $3{\cdot}8 \times 10^3 \pm 1100$ to $8{\cdot}6 \times 10^3 \pm 2000$ ($P < 0{\cdot}05$), and the differential count from 40 to 68 per cent. The unperfused medium had no such effect. Intact control animals treated with perfusate showed no significant rise in lymphocyte count.

GOLDSTEIN, A. L., and WHITE, A. (1970), in *Biochemical Actions of Hormones*, vol. I (ed. LITWACK, G.), p. 465. New York: Academic Press.

62. The Response of the Lower Oesophageal Sphincter to a Meat-extract Test Meal: G. R. GILES, A. ROSZKOWSKI, and P. J. GUILLOU, University Department of Surgery, St. James's Hospital, Leeds.

It has been suggested that gastro-oesophageal competence is largely determined by the pressures exerted by the lower oesophageal sphincter (L.O.S.) (Cohen and Harris, 1971). In an attempt to devise a test of sphincteric function L.O.S. pressures were assessed in response to a meat-extract test meal. Pressures were measured by a withdrawal technique repeated at intervals which results in a profile of the sphincter (10 normal subjects) or by continuously monitoring sphincteric pressures (8 normal subjects; 9 patients with hiatus hernia).

Almost all normal subjects showed increases in pressure following the test meal, reaching a peak after 30–60 minutes and then declining towards basal levels by the end of 2 hours. With the profile technique there was a mean percentage pressure increase over the basal levels of 20·0 per cent ± 9·0 by 30 minutes and 32·4 per cent ± 8·1 at 60 minutes. Continuous pressure monitoring was much more sensitive, with pressure increases of 86·7 per cent ± 24·9 at 30 minutes and 88·3 per cent ± 29·4 by 60 minutes. Patients with hiatus hernia showed diminished pressure increases of only 29·8 per cent ± 9·9 at 30 minutes and 36·8 per cent ± 11·7 by 60 minutes.

The meat-extract test meal demonstrates the poor sphincteric function in patients with hiatus hernia in a physiological manner and may prove useful in the clinical situation.

COHEN, S., and HARRIS, L. D. (1971), *New Engl. J. Med.*, **284**, 1053.

63. Diamine Oxidase and Histamine in the Small Intestine after Experimental Ischaemia: H. Richter, J. Kusche, K.-Th. Schumann, J. Schmidt, and W. Lorenz, Department of Experimental Surgery and Pathological Biochemistry, Surgery Clinic of the University Marburg/Lahn, Germany.

An altered balance of electrolytes and water and the formation and release of vaso-active substances can be observed in ischaemic gut. The concentrations of histamine and its inactivation by diamine oxidase (DAO) were measured in the small intestine of mongrel dogs before and following 10-hour ischaemia of the terminal ileum. Histamine was determined fluorometrically, the DAO activity by the spectrophotometric test with *o*-aminobenzaldehyde.

Before ischaemia the DAO activity and histamine concentration were 15·5 ± 5·7 mU. per g. and 17 ± 8 µg. per g. Following ischaemia the DAO activity was diminished in the ischaemic part of the ileum by 43 per cent ($P < 0·02$, $n = 8$), but increased in the non-ischaemic part by 75 per cent ($P < 0·01$). In the intestinal fluid the DAO activity was 21·7 ± 12·3 mU. per ml. in the ischaemic area and 61·3 ± 34·3 mU. per ml. in the non-ischaemic area ($P < 0·005$, $n = 10$). The histamine concentration remained unchanged in the ischaemic ileum, but decreased in the non-ischaemic ileum by 42 per cent ($P < 0·025$, $n = 8$). An inverse correlation existed between the DAO activity and the histamine concentration in the non-ischaemic small intestine before and after ischaemia ($r = -0·76$; $r = -0·99$).

Probably histamine released from the non-ischaemic gut was inactivated by DAO. This enzyme may protect the organism from histamine release into the circulation.

64. Glucagon in the Pathogenesis of Acute Pancreatitis: M. Knight (B. N. Brooke), Surgical Unit, St. George's Hospital Medical School, London.

There is evidence for the existence of a naturally occurring factor which retards the progression of acute pancreatitis by reducing pancreatic exocrine secretion. Glucagon decreases the volume and enzyme concentration of pancreatic juice, and hyperglucagonaemia has been noted in non-fatal experimental acute pancreatitis (Paloyan et al., 1966).

In this study plasma-glucagon levels were monitored during experimental pancreatitis induced in 6 dogs by the closed-duodenal-loop technique. This model produces oedematous pancreatitis at about 4 hours with sudden onset of fatal haemorrhagic pancreatitis and plasma-amylase elevation at about 10 hours.

An initial rise in plasma glucagon occurred which was maximal at a mean of 6¼ hours from operation. There then followed a fall in plasma glucagon maximal at a mean of 8¾ hours associated with hyperamylasaemia. A second rise in glucagon values occurred just before death. Average survival was 12½ hours. Six other dogs subjected to identical procedures received intravenous glucagon post-operatively. This treatment prolonged survival to a mean of 19 hours.

It is suggested that hyperglucagonaemia may be the factor which retards the progression of acute pancreatitis.

65. The Role of Vagal Release of Gastrin in Pancreatic Enzyme Secretion: W. H. Beesley, R. Orahood, P. Dutta, and M. M. Eisenberg (W. G. Fegan), Dublin and Minneapolis.

The vagal control of pancreatic enzyme secretion is known to be mediated by (1) direct extragastric vagal innervation of the pancreas, (2) vagal release of gastri from the stomach, (3) pancreozymin release consequer upon duodenal acidification. The relative importance these factors is uncertain.

Eight dogs were prepared with chronic gastric (G.P and pancreatic fistulas (P.F.).

A dose of 200 mg./kg. 2-deoxy-D-glucose was give intravenously as a vagal stimulus. Pancreatic juice wa collected every 15 minutes and gastric juice every 3 minutes for 4 hours. Pancreatic protein, bicarbonat and gastric HCl output were measured.

Four dogs underwent selective extragastric vagotom removing only direct extragastric pancreatic innervatio leaving intact vagal innervation to the stomach, an resulting in unaltered gastric acid production and vag release of gastrin. Four dogs underwent selective gastr vagotomy, removing vagal innervation to the parietal cel and gastric antrum, resulting in an almost zero vagal relea of acid, while preserving extragastric vagal innervation the pancreas.

The 4-hourly pancreatic protein output fell by 77 p cent following selective gastric vagotomy and by 15 p cent following selective extragastric vagatomy compar with control levels.

The reduction in output following elimination of vag release of gastrin, and of only 15 per cent when the gastr mechanism is intact, demonstrates that the vagal relea of gastrin is the major element in vagally stimulat pancreatic enzyme production and that direct extragastr vagal fibres are relatively unimportant.

66. Lysolecithin: A Factor in the Path genesis of Gastric Ulceration?: A. G. Johnso Charing Cross Hospital Medical School, London.

The regurgitation of bile-salts into the stomach has be proposed as a cause of gastric ulceration. The phosph lipid, lysolecithin, which is formed in the duodenum wh phospholipase A in pancreatic juice hydrolyses t lecithin in bile, is also a strong detergent and highly to to cell membranes. This study was designed to determi whether during the night lysolecithin occurs in sufficie concentration in the gastric juice of gastric ulcer patie to cause mucosal damage.

A nasogastric tube was positioned at 9.30 p.m. by t water-recovery method, 3 hours after a normal hospi supper, and 10-ml. samples taken at 2-hourly interv throughout the night. Lysolecithin was measured silicic acid chromatography (Borgstrom, 1957) and purity confirmed by thin-layer chromatography.

Twenty-seven patients were studied. The mean of t peak concentrations (483 µg. per ml.) and mean of samples (212 µg. per ml.) for gastric ulcer patients w significantly higher ($P < 0·001$) than for normal cont patients (36 µg. per ml. and 23 µg. per ml. respectivel Duodenal ulcer patients had normal or slightly rais levels. The values found in gastric ulcer patients similar to those causing mucosal damage under expe mental conditions (Davenport, 1970) and it is conclud that lysolecithin may be as important or more import than bile-salts in the aetiology of gastric ulceration.

Borgstrom, B. (1957), *Acta chem. scand.*, **11**, 749.

67. Effect of Secretin on Pentagastri stimulated Myoelectrical Activity of t Stomach: B. S. Bedi, I. H. Khan, and K. Kelly, University Department of Surgery, Weste Infirmary, Glasgow, and Mayo Clinic, Rochest Minnesota.

There is evidence that secretin inhibits spontane electrical activity of the stomach. The purpose of t study was to investigate the effect of secretin on pen gastrin-stimulated gastric myoelectrical activity.

Three dogs were prepared with chronically implanted Ag–AgCl electrodes on the serosal surface of the stomach. Electrical recordings were made in fully conscious dogs. Pentagastrin and secretin, alone or in combination, was given by continuous intravenous infusion over 20 minutes. Dose–response studies to both pentagastrin and secretin were first made; the doses used ranged from 0·0015 to 0·048 μg. per kg. per min. for pentagastrin, and from 0·025 to 0·39 unit per kg. per min. for secretin. The effect of combined pentagastrin and secretin was studied at maximal and submaximal doses. Four observations were made on each dog using each dose of secretin and pentagastrin.

There was a dose-related increase in the frequency of pace-setter potentials with pentagastrin infusion. Secretin by itself had no influence on the frequency of the pace-setter potential. Small doses of secretin inhibited pentagastrin-stimulated action potentials but did not affect the frequency of the pace-setter potentials. The kinetics of the dose–response relationship between secretin and pentagastrin suggest that secretin blocks the action of pentagastrin on gastric myoelectrical activity in a non-competitive manner.

68. Histamine Release from the Liver by Trypsin: R. Tauber, R. Uhlig, G. Mann, A. Schmal, and W. Lorenz, Department of Experimental Surgery and Pathological Biochemistry, Surgery Clinic, University of Marburg/Lahn, Germany.

Histamine release is probably involved in various pathophysiological processes observed in the abdomen, such as stress ulcers, acute pancreatitis, ileus, or during liver transplantation. Proteolytic enzymes, such as trypsin, kallikrein, and trypsin-like lysosomal proteases mainly, are considered to cause this histamine release.

As a model for these processes the quantitative aspects and the site of histamine release by trypsin (5 mg. per kg. i.v. into the femoral vein) was investigated in 9 male anaesthetized mongrel dogs (14–25 kg.) by the fluorometric determination of histamine in plasma and whole blood of the ventral aorta, portal vein, hepatic veins, and inferior vena cava. In the plasma of the inferior vena cava the histamine concentration rose from 0·5 ± 0·3 to 16·2 ± 12·2 ng. per ml. ($P < 0{\cdot}02$), and in the whole blood from 42 ± 32 to 102 ± 74 ng. per ml. at the time of maximum hypotension following the injection of trypsin. Since only plasma histamine, but not whole-blood histamine, is free and vasoactive, the majority of released histamine was very rapidly inactivated by an uptake into the erythrocytes.

In the hepatic veins the histamine concentration of the whole blood rose from 44 ± 30 to 835 ± 620 ng. per ml., in the ventral aorta from 45 ± 37 to 340 ± 280 ng. per ml., and in the portal vein from 43 ± 30 to 114 ± 84 ng. per ml., indicating that histamine release by trypsin occurred preferably in the liver.

It is assumed that the erythrocytes play an important role in the rapid inactivation of histamine released by proteolytic processes, and that the liver is one of the target organs for this release.

69. Effect of Renal Revascularization by Splenic Artery Implantation on Experimental Renovascular Hypertension: J. F. O'Grady and F. A. Reichle (J. P. McMullin), Saint Vincent's Hospital, Philadelphia.

Recently prolonged patency of experimental splenic artery implants (S.A.I.) into the ischaemic renal cortex has been demonstrated. Conflicting data regarding the effect of such implants on renovascular hypertension in the dog have been reported (Lanier et al., 1970).

The effect of S.A.I. on blood-pressure in a large number of rats with renal artery stenosis (R.A.S.) was tested. Left R.A.S., S.A.I. into the renal cortex, and contralateral nephrectomy were performed on forty 150-g. male Holtzman rats. Forty additional animals had left R.A.S., right nephrectomy, and no S.A.I. Prolonged patency of the S.A.I. was confirmed in some animals by angiography or at post-mortem examination.

Over 800 individual systolic blood-pressure determinations were performed by Doppler auscultation over the ventral aspect of the rat tail distal to a sphygmomanometer cuff. Significantly less hypertension was noted beginning 30 days postoperatively and throughout the extent of follow-up (90 days) ($P < 0{\cdot}01$ or $P < 0{\cdot}02$ at every 10-day interval).

Extrarenal arterial implantation into the ischaemic renal cortex of the rat does exert a significant anti-hypertensive effect.

Lanier, V. C., Van Way, C. W., Tyree Finch, W., Manlove, A., Michelakis, A. M., and Foster, J. H. (1970), *Surg. Forum*, **21**, 175.

70. The Production of Experimental Chronic Myocardial Infarction leading to Left Ventricular Failure in the Dog: W. Lloyd Jones, S. Smith, J. Serur, E. H. Sonnenblick, and F. H. Ellis, jun. (D. Annis), Lahey Clinic Foundation, Peter Bent Brigham Hospital, Boston, and Liverpool Royal Infirmary.

Chronic myocardial infarcts were produced in 18 adult dogs by a two-stage coronary artery ligation and agar injection technique.

At the first operation the anterior descending branch was ligated near its origin from the left coronary artery and plain agar (1·5 per cent) at 37° C. was injected distally. Four weeks later, through a second thoracotomy, one or more of the left circumflex apical branches was ligated and injected distally with agar.

Immediate mortality was 5 per cent (1/18) following the first operation, 15 per cent (3/18) following the second operation, and 15 per cent during the convalescent period. The surviving 11 animals showed decreased exercise tolerance with increased heart size and pulmonary congestion on chest radiographs.

Left ventricular catheterization under morphine sedation 5–8 weeks after the second infarction revealed a marked elevation of the left ventricular end diastolic pressure (mean 40 mm. Hg) with a reduction in cardiac output and ejection fraction. Left ventricular cine-angiography performed concurrently in all dogs showed akinetic areas on the antero-apical cardiac surface involving 25–35 per cent of the end diastolic perimeter.

Post-mortem examinations revealed changes of transmural infarction involving 20–35 per cent of the left ventricular surface area, whilst the lung tissue showed evidence of long-standing pulmonary congestion.

71. Contractility and Compliance-elasticity Studies in Arterial Vein Autografts: W. G. Waddell, I. J. Vogelfanger, V. Moonje, K. U. Malik, M. MacConaill, and G. Ling, Department of Surgery, Faculty of Medicine, University of Ottawa, Ottawa, Ontario.

The right lateral saphenous vein was used as an arterial autograft in the ipsilateral femoral artery in 28 unselected mongrel dogs. Four animals were studied immediately after operation. Three groups of 8 dogs were studied 2, 5–7, and 13–15 months postoperatively.

In each instance the vein autograft was compared with the normal lateral saphenous vein and the normal femoral artery from the contralateral hindlimb. Helically cut strips of the vessel wall were placed in suitably maintained muscle-baths and contractility was measured isotonically by recording the change in length induced by increasing doses of noradrenaline (10^{-9} to 5×10^{-5} mg. per ml.). The vessel strips were placed under slight tension and compliance and elasticity were determined by recording the change in length and recoil in response to changes in tension (500 mg. to 2·0 g.).

There is an approximately sixfold decrease in contractility in the arterial vein autografts 5–7 months postoperatively and about 35 per cent reduction in compliance and elasticity over 1 year after operation in comparison with normal lateral saphenous veins. If the latter observation proves to be progressive with longer periods of follow-up, stiffening of the vein-grafts may explain late graft failure, particularly in situations where continued flexibility is required.

72. **Prolonged Left-heart By-pass without Anticoagulation:** C. R. W. GRAY, J. S. BAILEY, and C. E. DREW (H. Ellis), Cardiothoracic Department, Westminster Hospital, London.

During the past 5 years a ventricular-type pump has been developed which is unique in that the ventricle, valves, and cannulae are formed from a single silicone-rubber moulding. The surface presented to blood is smooth, making anticoagulation unnecessary.

The drive system is hydraulic so that in the event of rupture of a silicone part, blood can only mix with normal saline. The control system is pneumatic and permits independent variation of systolic and diastolic duration and stroke volume.

Thirty-five experiments have been performed on calves. By-pass from left atrium to aorta was attempted for 24 hours. The by-pass was then discontinued and the animal allowed to survive. Monitoring of blood-pressures, blood-gases, and haematological and biochemical parameters was performed throughout by-pass. Post-mortem histological studies were carried out.

The action of the pump during by-pass was examined on cine-film.

73. **Low Doses of Heparin in the Prevention of Postoperative D.V.T.—A Double-blind Trial:** D. P. FOSSARD, T. CORRIGAN, J. J. SPINDLER, and V. V. KAKKAR (C. T. Howe), Department of Surgery, King's College Hospital Medical School, London.

It has been suggested that low doses of heparin reduce the incidence of postoperative venous thrombosis (Kakkar et al., 1971). All these papers are open to criticism on the grounds that the diagnosis of D.V.T. was made clinically or that the trial was not controlled.

Sixty-three patients over the age of 40 years undergoing major elective surgery were studied, using the ^{125}I-fibrinogen uptake technique to diagnose venous thrombosis. Patients received either calcium heparin, 5000 units subcutaneously, 2 hours before operation and then twice daily for 7–10 days, or a placebo administered similarly. Selection of patients for treatment or placebo was randomized and neither the physicians in charge of the patients nor those concerned with diagnosis of D.V.T. knew which 'drug' the patients had received.

Thirty-four patients received the placebo, of which 14 (41 per cent) developed venous thrombosis, and 29 patients received heparin, of which 2 (7 per cent) developed venous thrombosis. These results are statistically significant ($P < 0.005$).

KAKKAR, V. V., FIELD, E. S., NICOLAIDES, A. N., FLUTE, B. J., WESSLER, S., and YIN, E. T. (1971), *Lancet*, **2**, 671.

74. **Soleal Veins and Local Fibrinolytic Activity:** A. N. NICOLAIDES, C. T. CLARK, R. D. THOMAS, and J. D. LEWIS (C. W. Jamieson), Surgical Unit, St. Mary's Hospital, London.

Recent studies have demonstrated that practically all postoperative thrombi start in the soleal veins where stasis occurs (Nicolaides et al., 1971). It has been suggested that diminished local fibrinolytic activity may be an additional local factor predisposing to thrombosis (Brown et al., 1971). The purpose of the present study was to compare the fibrinolytic activity present in the soleal veins with the activity of the popliteal and femoral veins using a histochemical technique.

Samples of soleal, popliteal, and femoral veins were obtained from 6 cadavers within 36 hours from death. Cryostat sections were mounted on slides with fibrin films and incubated for 5, 10, 20, 30, 40, 60, and 90 minutes at 37° C. Sections from all three veins from the same cadaver were mounted on the same slide. The time at which lysis first occurred was determined.

The results showed that the incubation times required to produce lysis by the popliteal and femoral veins were always the same for each set of veins. However, there was always delay in the appearance of lysis in the soleal veins. This delay was 5 minutes in 1, 20 minutes in 3, 30 minutes in another, and 70 minutes in the remaining specimen.

In a separate experiment with veins obtained at operation it was determined that storing the vein in serum at 4° C. (to simulate cadaveric conditions) for 36 hours did not alter its fibrinolytic activity.

These preliminary results suggest that there may be diminished fibrinolytic activity in the soleal veins and this may be an additional local factor predisposing to the initiation of thrombi and their subsequent extension.

75. **Small Doses of Subcutaneous Heparin preventing Deep-vein Thrombosis in Major Surgery:** A. N. NICOLAIDES, P. DUPONT, N. DOUGLAS, J. D. LEWIS, S. DESAI, and C. W. JAMIESON, Surgical Unit, St. Mary's Hospital, London.

It has been demonstrated recently that small doses of subcutaneous heparin can prevent deep-vein thrombosis in surgical patients (Kakkar et al., 1971). Previous studies involved small numbers of patients undergoing minor operations. The purpose of the present study was to determine the effectiveness of subcutaneous heparin in preventing venous thrombosis in a large series of patients undergoing major general and thoracic operations which carry a high risk of deep-vein thrombosis.

All the patients were over the age of 40 and were scanned with the ^{125}I-fibrinogen test. Two hundred and twelve patients have been studied to date. They were classified as general surgical or thoracic and then randomly allocated to a control or test group. Both groups received the routine preventive measures practised in this hospital (elastic stockings, supervised leg exercises, and early mobilization). In addition, subcutaneous sodium heparin (5000 units in 0·2 ml.) was administered to the test group 2 hours before operation and then 12-hourly for 7 days. Twenty-three (22 per cent) out of the 105 in the control group developed deep-vein thrombosis, while 1 of the 107 patients in the test group did. This is highly significant (Fisher's exact test $P = 0.000036$).

The preliminary results of this trial indicate that small doses of subcutaneous heparin are most effective in preventing deep-vein thrombosis in patients undergoing major general and thoracic operations.

76. Turbulence as a Factor in the Aetiology of Varicose Veins: A. L. KLINE and P. BYRNE (W. G. Fegan), Department of Clinical Surgery, Sir Patrick Dun's Hospital, Dublin.

Although patients with marked symptoms and signs of calf-muscle-pump dysfunction have varicose veins they are almost insignificant especially when compared with the gross varicosity displayed by many asymptomatic varicose patients.

The flow characteristics in superficial veins of two groups of ambulatory patients were studied.

Group I: Ten asymptomatic patients with gross varicosity of the long saphenous vein and its tributaries.

Group II: Ten patients with marked symptoms and signs of muscle-pump dysfunction with minimal varicose veins.

The results obtained were compared with those of 10 normal students.

In both pathological groups reverse flow was demonstrated but was absent in normal patients. Although the velocity and duration of this reverse flow were far greater in group I, the most significant difference between the two groups was the fact that turbulence was present in the flow of the asymptomatic patients with gross varicosities. Turbulence was detected with an accelerometer (Gosling and King, 1969) and also by analysis of the audio signal from the Doppler ultrasound equipment. Turbulence was not found in the symptomatic patients (group II or the normal patients).

Turbulent retrograde flow may be responsible for vessel-wall changes resulting in sacculation and tortuosity.

SHORT NOTES OF RARE OR OBSCURE CASES

BILATERAL TRAUMATIC RENAL ARTERY OCCLUSION WITH SURVIVAL AFTER LATE RECONSTITUTION OF ARTERIAL FLOW

BY W. E. BIRKENSTOCK, R. RABKIN, AND D. P. STABLES

DEPARTMENTS OF SURGERY, MEDICINE (RENAL UNIT), AND RADIOLOGY, GROOTE SCHUUR HOSPITAL AND UNIVERSITY OF CAPE TOWN, SOUTH AFRICA

SUMMARY

Survival after bilateral traumatic renal artery occlusion is uncommon. A patient is described who recovered useful renal function despite a 12-hour delay in reconstitution of arterial flow. Postoperative oliguria lasted 45 days, necessitating prolonged haemodialysis.

TRAUMATIC renal artery occlusion is being detected with increasing frequency (Steiness and Thaysen, 1965; Grablowsky, Weichert, Goff, and Schlegel, 1970; Evans and Mogg, 1971). The occasional attempt (Steiness and Thaysen, 1965; Grablowsky and others, 1970) at restoring blood-flow to the kidney has failed and the usual treatment is nephrectomy. As there is experimental evidence (Hamilton, Phillips, and Hiller, 1948; Steuber, Kouvacs, Koletsky, and Persky, 1958) that after 3 hours of total arterial occlusion the normothermic dog kidney may, and after 8 hours will, lose viability it might seem futile to attempt operation in traumatic arterial occlusion if there is considerable delay. We therefore report a case of complete bilateral traumatic renal artery occlusion to emphasize that useful renal function can be salvaged even 12 hours after injury.

CASE REPORTS

A 16-year-old coloured girl was brought to hospital between 1½ and 2 hours after a motor-vehicle accident. Physical examination revealed fractures of the pelvis, left loin tenderness, absence of bowel-sounds, and severe hypotension. The bladder contained less than 30 ml. of blood-stained urine. Cystography excluded bladder rupture. Because of difficulty in the correction of her hypotension and delay in the performance of excretion urography, which showed no excretion of contrast medium, abdominal aortography was performed 9 hours after injury. This demonstrated occlusion of both renal arteries within 2 cm. of their origins with irregular contours suggestive of intimal tears (*Fig.* 1).

At operation 10½ hours after injury bilateral renal artery occlusion was confirmed. The right renal artery was thrombosed from approximately 1½ cm. from its origin to its bifurcation (*Fig.* 2 A).

This was explored first through a longitudinal arteriotomy and thrombus was extracted. The intima and media were found to be disrupted and folded up distally causing complete occlusion. These were teased back, sutured to the adventitia, and the arteriotomy closed with a Dacron patch (*Fig.* 2 B). Good distal pulsation was palpable.

The left renal artery was avulsed except for a thin strand of adventitia posteriorly (*Fig.* 2 A). Thrombus was extracted from both ends of the vessel and 1–2 cm. of damaged artery were excised prior to mobilization of the kidney and end-to-end anastomosis (*Fig.* 2 B). Pulsatile flow was restored and a left renal biopsy produced brisk bleeding. A tear in the left renal vein was sutured.

Bilateral retroperitoneal haematomas were present. Small bowel which had been rendered ischaemic by a mesenteric tear was resected.

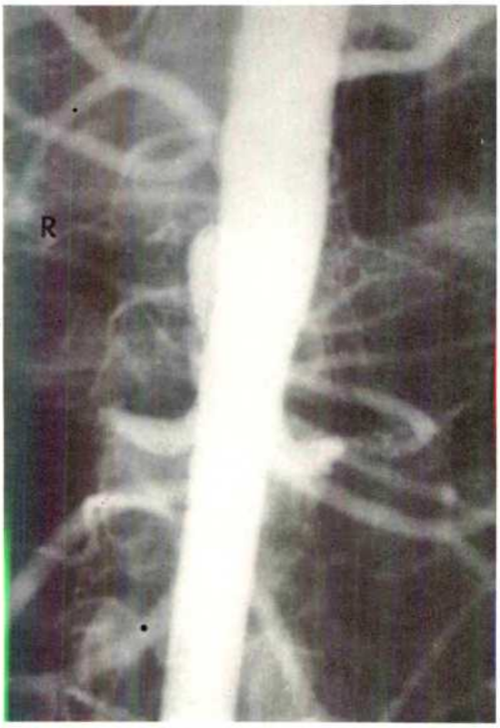

FIG. 1.—Preoperative arteriogram.

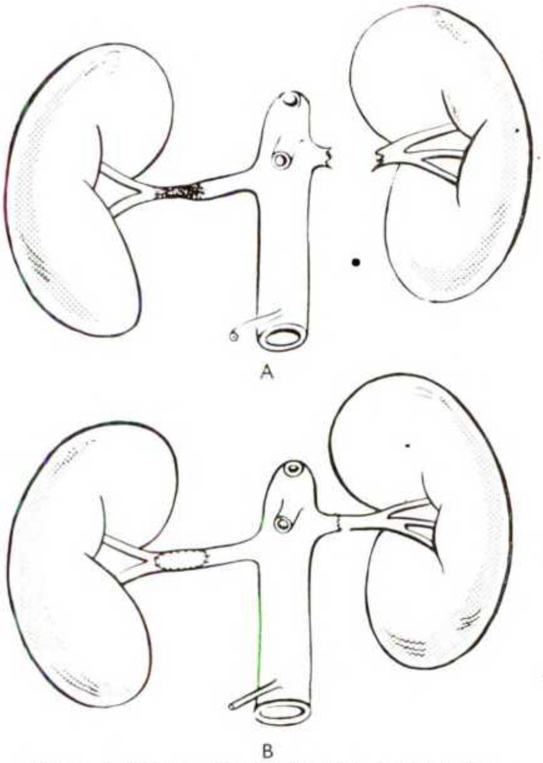

FIG. 2.—A, Diagrammatic appearance of operative findings. B, Postoperative appearance.

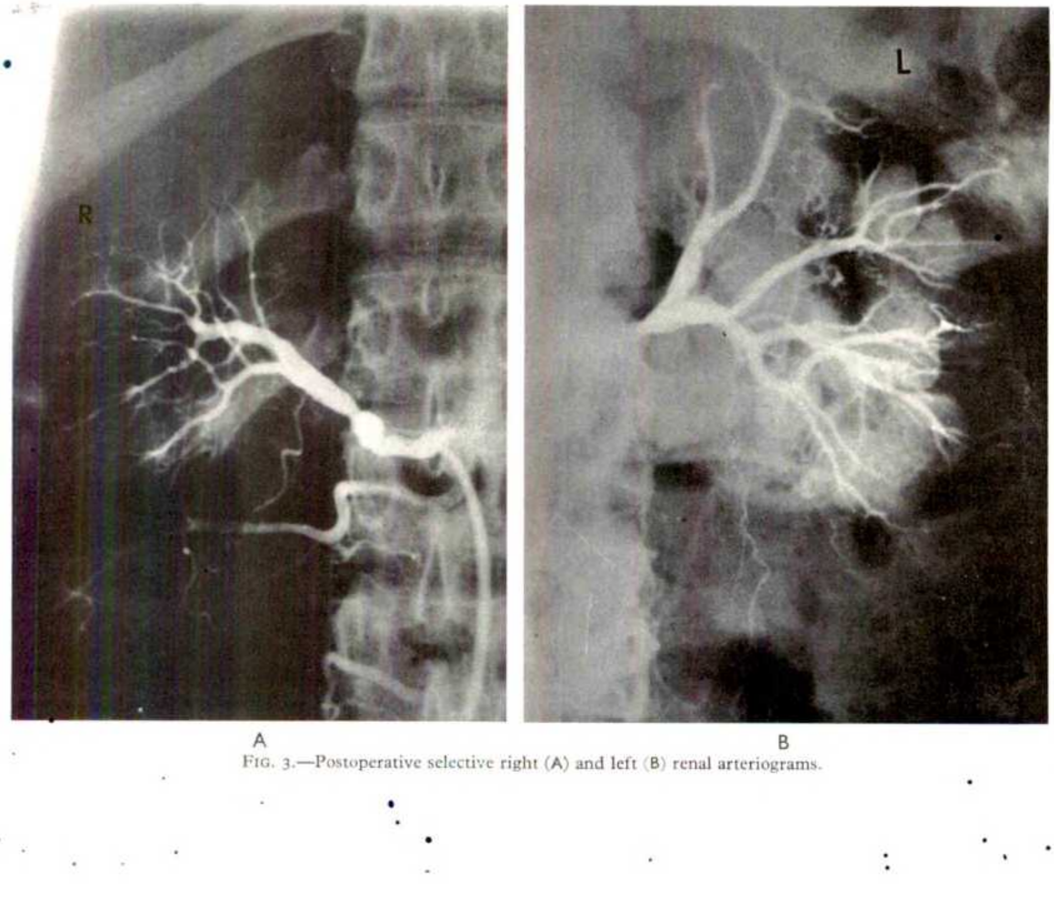

A B

FIG. 3.—Postoperative selective right (A) and left (B) renal arteriograms.

Histology of the left renal biopsy specimen showed capillary congestion, interstitial and tubular oedema, and some tubular necrosis.

Selective renal arteriography 36 days after operation showed patent renal arteries with moderate stenoses at their sites of repair (*Fig.* 3). All of the right renal segmental arteries were patent but the posterior division of the left renal artery was occluded. Two subsequent excretory urograms showed excretion of contrast medium by the right kidney only. This finding was confirmed with an isotope renogram.

The postoperative course was complicated by recurrent infections of a thigh wound, a pulmonary infarct, and a urinary-tract infection. The oliguric phase lasted 45 days, being particularly severe for the first 11 days, daily urine output being less than 100 ml. (*Fig.* 4). Haemodialysis was repeated frequently to control uraemia and hyperkalaemia and to allow a 40-g. protein intake from the eighth day onwards. The last haemodialysis was performed on the sixty-fifth day and thereafter the patient was maintained on the same diet with unrestricted fluids. She returned to a reform school for juvenile delinquents, and as she is extremely uncooperative it is likely that her protein intake has increased. Four months after injury menses returned; at that time the creatinine clearance was 6 ml. per minute per 1·73 m^2., serum creatinine, 8·8 mg. per 100 ml.; and the blood-urea, 230 mg. per 100 ml. When last seen 186 days after the accident she was fully active, looked well, was normotensive, and her urine was sterile. The serum creatinine was 7·1 mg. per 100 ml.; the blood-urea, 203 mg. per 100 ml.; and the haemoglobin, 10 g. per 100 ml.

DISCUSSION

The operation on this patient was life-saving since her uncooperative behaviour and psychopathic personality would have prevented her acceptance for a renal transplantation or a chronic dialysis programme. Despite a 12-hour delay in the restoration of main arterial flow she recovered sufficient renal function to leave hospital and resume her normal activities. This result is all the more remarkable because the postoperative urograms indicated that the right kidney is responsible for most, if not all, of her renal function.

The explanation for the recovery of function must lie in the perfusion of some nephrons through collateral vessels (Brest, Bower, and Heider, 1964; Perkins, Jacobsen, Feder, Lipchik, and Fine, 1967) during the period of complete artery occlusion. Failure of the preoperative aortogram to demonstrate this collateral circulation in no way excludes its presence. The potential collateral pathways through capsular, adrenal, and ureteric arteries are small and these vessels are difficult to define on good-quality aortogram films in normal subjects, let alone those obtained after severe abdominal trauma. Relatively little blood-flow need be postulated as arterial pressures below the levels required for glomerular filtration are adequate to maintain viability of renal parenchyma (Morris, Heider, and Moyer, 1955).

Recovery of renal function after even longer delays in surgical correction has been described in spontaneous renal artery occlusion by emboli (Morris and others, 1955; Brest and others, 1964). In such cases it is likely that an extensive collateral circulation had been stimulated by a previously compromised renal circulation. The capacity of the collateral pathways to widen in chronic renal ischaemia has been emphasized by Brolin and Stener (1966), who described a patient in whom one renal artery was occluded and yet the kidney excreted contrast medium normally and was normal in size.

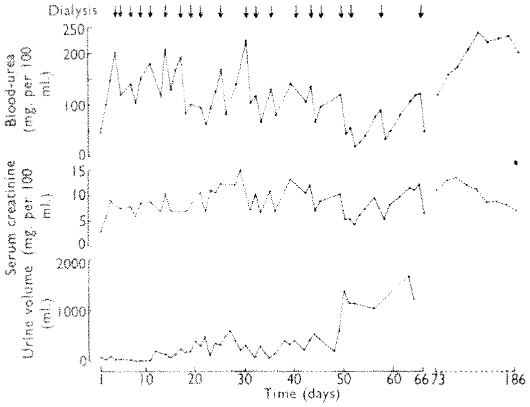

FIG. 4.—Postoperative course.

In the present case once patency of the renal arteries had been confirmed by postoperative arteriography a prolonged period of intermittent haemodialysis was necessary. Equally long or longer oliguric phases have been described in patients recovering from acute cortical necrosis (Walls, Schorr, and Kerr, 1968). Also described in acute cortical necrosis (Rieselbach, Klahr, and Bricker, 1967; Walls and others, 1968) is the slow improvement in renal function noted in our patient. This improvement has been attributed to functional adaptation of the surviving nephrons rather than to an increase in the functioning nephron population (Rieselbach and others, 1967). Further improvement in our patient's renal function is possible so long as she remains normotensive.

ACUTE MYELITIS PRESENTING AS SPASTIC COLONIC ILEUS

By H. T. WILLIAMS and D. T. L. TURNER

ST. GEORGE'S HOSPITAL, LONDON

SPASTIC ileus of the large bowel is seen occasionally in surgical practice and reports have been published of a variety of causes (Caves and Crockard, 1970; Watkins, 1970). We wish to record a further example of this condition which was due, we believe, to an acute viral myelitis and which preceded the onset of other neurological signs by 11 days.

CASE REPORT

R. T., a Civil Service clerk aged 57 years, was admitted with a 4-day history of abdominal pain. The pain had been of gradual onset, was constant, and was situated in the left iliac fossa. There had been no bowel action since the onset of the pain but he had passed a little flatus. He had previously been in good health.

On examination the patient was moderately obese with a pyrexia of 37·5° C. There was some abdominal distension with tenderness in the left iliac fossa but no masses were palpable. Rectal examination revealed moderate benign prostatic enlargement only. No abnormality could be detected in the cardiovascular, respiratory, or central nervous systems.

Plain abdominal radiographs showed gas in the proximal colon with slight distension of the small bowel. A provisional diagnosis of acute diverticulitis was made and the patient was treated with nasogastric suction, intravenous fluids, and antibiotics. During the ensuing 8 hours his pain became more severe, central, and colicky. There was increasing abdominal distension and obstructive bowel-sounds were heard. A repeat abdominal radiograph showed distension of the large bowel down to the sigmoid colon with fluid levels in the proximal colon; there was also some distension of the small bowel with a few fluid levels. Enemata failed to relieve the distension and therefore a laparotomy was performed.

At operation the large bowel was found to be uniformly distended but there was no evidence of any mechanical obstruction. The bowel wall was not inflamed and there were no signs of an ischaemic episode. A flatus tube was passed up from the anus, and the left colon was partially decompressed manually. A decompression needle was used in an attempt to deflate the caecum but this was only partially successful. Owing to the spasticity of the wall the bowel did not deflate normally. The flatus tube was left in situ and the abdomen was closed.

Post-operatively the patient remained chronically distended but this gradually improved after 2 days when he began to pass small amounts of flatus spontaneously. On the eighth day he developed painless retention of urine and this was followed a few hours later by a progressive flaccid paralysis of his lower limbs. Sensation was also impaired below D.V.10. Myelography revealed no block in the subarachnoid space, but the cerebrospinal fluid was found to contain the following: white blood-cells, 640 per c.mm. (mainly polymorphs); red blood-cells, less than 1 per c.mm.; protein, 20 mg. per 100 ml. No organisms were seen on film or were subsequently cultured.

During the next week there was a gradual return of power and sensation in the lower limbs and after 2 weeks the patient was able to stand with assistance although he was unable to walk. A cystometrogram showed normal bladder sensations but the tone was reduced. There was no abdominal distension but bowel action was achieved only with the aid of enemata. He continued to improve over the following 3 weeks. A further cystometrogram showed normal bladder tone and after the removal of the catheter he passed urine spontaneously with good control and little residue. Spontaneous bowel action had also returned and the patient was walking with the aid of a frame. A repeat lumbar puncture 4 weeks after the first showed clear fluid with normal pressure. The fluid now contained: white blood-cells, 9 per c.mm.; red blood-cells, less than 3 per c.mm.; protein, 150 mg. per 100 ml.; a Lange's test was negative. The patient was discharged 11 weeks after admission, having normal bladder and bowel function and walking with the aid of one stick only.

DISCUSSION

Spastic ileus or pseudo-obstruction of the large bowel is seen infrequently. Since Ogilvie first described the syndrome in 1948 it has been noted in association with intra-abdominal inflammation, retroperitoneal disease, cardiac failure, coronary thrombosis, systemic infection, and following traumatic lesions of the spinal cord. There has also been a number of cases where no aetiological factor has been demonstrated. The present case was initially placed in the idiopathic category until the development of paraparesis. This, however, did not occur until 11 days after the onset of bowel symptoms. Cord decompression having been excluded by the myelogram, the diagnosis lay between spinal artery thrombosis, acute myelitis, and multiple sclerosis. Acute myelitis now seems the most probable because of the protein and polymorphs in the cerebrospinal fluid and because of the subsequent recovery of function. We have been unable to find any previous record in the literature of acute myelitis presenting initially as a large-bowel ileus.

Acknowledgements.—We are most grateful to Mr. R. P. Rosswick for permission to publish this case and for advice in the preparation of this report. Miss C. F. Steptoe rendered invaluable secretarial assistance.

RUPTURED SOLITARY CYST OF THE LIVER

By R. C. G. RUSSELL

DEPARTMENT OF SURGERY, THE MIDDLESEX HOSPITAL, LONDON

SUMMARY

A further case of a ruptured solitary cyst of the liver is described. A brief review of the 7 previously described cases is given. The management of the condition is discussed, and surgical treatment by either total excision or excision of the roof of the cyst is recommended.

SIR BENJAMIN BRODIE in 1846 described seeing a young lady with a cystic tumour of the right upper abdomen which disappeared after aspiration of 2 pints of clear watery fluid. This case has been considered to be the earliest report of a solitary cyst of the liver, but as it was not authenticated by operative or post-mortem findings the first definitive report is said to be that of Michel in 1856.

Table I.—DETAILS OF THE PREVIOUSLY REPORTED CASES OF RUPTURED SOLITARY CYST OF THE LIVER

CASE	AUTHOR	AGE AND SEX	CLINICAL FEATURES	OPERATIVE FINDINGS
1	Davis (1937)	67 F.	10-day history of severe abdominal pain, with mass palpable in the abdomen for many years On examination distended abdomen with generalized tenderness	Tan-coloured fluid in the peritoneal cavity; large cyst in the right lobe of the liver. Cyst excised; satisfactory postoperative recovery
2	Lulenski (1948)	42 F.	Recurrent epigastric pain for 3 years; sudden severe pain with nausea and vomiting On examination generalized abdominal tenderness	100 ml. grey-green fluid with moderate peritoneal reaction; 4 × 4 × 6-in. cyst in posterior inferior surface of left lobe. Cyst deroofed with satisfactory recovery
3	Horton (1954)	44 F.	Continuous aching abdominal pain for 3 days after striking abdomen On examination generalized abdominal pain with mass palpable	Laparotomy revealed ruptured liver cyst. No procedure, but later enucleation of cyst performed with satisfactory result
4	Morgenstern (1959)	56 F.	Sudden epigastric pain On examination moderately shocked with diffusely tender abdomen	3–4 litres dark greenish fluid; 35-cm. cyst in left lobe of liver. Left lobectomy performed; recovery satisfactory
5	Johnston (1960)	82 F.	Right-sided abdominal pain with vomiting On examination ill with tense abdomen, maximum on the right side	Reddish-brown fluid; 15-cm cyst in the right lobe of liver. Catheter drainage; died on third postoperative day
6	Sachs and Robbins (1967)	81 M.	Known case of liver cyst being treated by aspiration. Presented with vomiting and generalized guarding. Treated conservatively. Died on thirteenth day after admission	Post-mortem examination showed a ruptured liver cyst in the inferior surface of liver with fistulous tract into a duodenal ulcer
7	Govostis (1969)	70 M.	Known case of liver cyst. Presented with abdominal pain and generalized guarding	Chocolate-brown fluid; a large cyst in the right lobe treated by drainage. Recovery satisfactory

Since then about 350 cases have been described in the English literature, the condition having been reviewed by Davis in 1937, Geist in 1955, and Flagg and Robinson in 1967.

The term 'solitary cyst of the liver' is specific. It should not be confused with retention, degenerative or other distinctive cysts found in the liver, or with polycystic disease of the liver. Geist (1955) in his review limited the term to single cysts, or at the most not occurring in more than two or three isolated portions of the liver, with typical gross and microscopic appearances. The cyst although solitary may be multilocular. Macroscopically the cyst has a smooth wall, up to 7 mm. thick, is greyish or greyish-green in colour, and contains a clear and serous or dark and viscid fluid. Microscopically three layers are recognized, namely an outer collagenous layer containing muscle-fibres, bile-ducts, and compressed hepatic cells, a middle layer containing vascular elements, and an inner layer of tall, columnar epithelium, mucus-producing epithelium, ciliated epithelium, or squamous epithelium.

The solitary cyst of the liver is usually asymptomatic, but the following complications do occur: bleeding into the cyst (Ackman and Rhea, 1931); jaundice which according to Flagg and Robinson (1967) occurs in 9 per cent of cases; secondary infection of the contained fluid (Greig and Stinson, 1961); hepato-cysto-enteric fistula (Sachs and Robbins, 1967); torsion of the cyst (Orr and Thurston, 1927); rupture of the cyst. Rupture is a rare complication, only 7 cases being recorded in the English literature. An account is given of a further case.

CASE REPORT

Mr. L. A., aged 68 years, was admitted as an emergency on 21 Sept., 1969, with severe abdominal pain. One week prior to admission he had had a sudden severe epigastric pain which had lasted for 2 hours, leaving a dull ache in the epigastrium for a period of 4–6 hours. He had then been well and at work until the day of admission, when after a light lunch he had felt severe pain in the lower sternal region which had radiated to the epigastrium and to the back. He had vomited twice. On admission he was in considerable pain and had a pyrexia of 37·8° C., a tachycardia of 110, and a normal blood-pressure of 130/90 mm. Hg. The abdomen was tender throughout with maximum tenderness in the upper epigastrium. No mass was palpable. Investigations showed a normal white blood count, a normal serum amylase, and radiographs of the chest and abdomen were within normal limits.

A diagnosis of a perforated duodenal ulcer was made and a laparotomy was performed. A ruptured solitary cyst of the liver was found, with a greenish-brown fluid in the peritoneal cavity. The cyst was situated in the left lobe of the liver, measured 12 cm. in diameter, and was thin-walled, being covered on the left lateral side by omentum which was adherent to the site of the perforation. A left lobectomy flush with the falciform ligament was performed. Pathological examination confirmed this to be a solitary cyst of the liver with many bile-ducts in the outer layer of the cyst wall.

Postoperative recovery was uneventful apart from wound dehiscence on the ninth postoperative day. When seen at follow-up 6 months later the patient was well and there was no abnormality on abdominal examination.

DISCUSSION

A summary of the previously reported cases of ruptured solitary cyst of the liver is given in *Table I*. Each presented as an acute abdomen. In *Cases* 6 and 7 the presence of a liver cyst was known and therefore rupture of the cyst was strongly suspected. In *Cases* 1 and 3 a mass was palpable, but in the remaining 3 cases there were no features to aid diagnosis, hence the need for laparotomy to determine the diagnosis.

At laparotomy the diagnosis is obvious but the main problem is to determine the correct surgical treatment for the ruptured liver cyst. The following measures have been advocated for treating solitary cysts of the liver: simple aspiration, total excision, marsupialization, external drainage, internal drainage into either the stomach or a Roux-en-Y loop of small bowel, and excision of the dome of the cyst with oversewing of the edges.

The general consensus has been that the cyst should be totally excised, whenever possible, by lobectomy or enucleation. Enucleation of the larger cysts, particularly if intrahepatic, is dangerous as the deeper part of the cyst may be adherent to the hilar structures which may be damaged if enucleation is attempted. For those cysts which lend themselves to total excision, namely those in the left lobe of the liver and those which are superficial on the anterior inferior surface of the right lobe, total excision is the procedure of choice. In all other instances excision of the roof of the cyst with oversewing of the edges is recommended, and this operation is particularly applicable to the ruptured liver cyst as it presents little technical difficulty and gives rise to few complications; these factors are of considerable importance as rupture of a liver cyst presents as an emergency when the full resources necessary for more major procedures may not be available. Belcher and Hill (1969) had no complications with this treatment in 3 cases which were followed up for 18, 15, and 1 year, respectively. Longmire, Passaro, and Joseph (1966) warn that on the rare occasion when bile is present in the cyst external drainage should be performed. Whatever method of treatment is undertaken care must be taken to break down all the loculi of the cyst otherwise there will be a recurrence (Rosenberg, 1956).

The operative mortality is low. Clark, Marks, Bernhard, and Bunfeldt (1967) estimated a mortality of 2·1 per cent for the surgical treatment of the uncomplicated solitary liver cyst. Despite the low mortality, Sanders and Garrett (1968) urge conservative treatment for solitary liver cysts which have been diagnosed clinically with compatible radiological signs and liver scans. Caplan and Simon (1966), in a review of the radiological signs, stress the inaccuracy of diagnosis and the need for surgical confirmation. There are, therefore, two reasons for urging surgical treatment of all suspected liver cysts, namely confirmation of the diagnosis and prevention of complications, as is illustrated by *Case* 6 in *Table I*. Complications undoubtedly increase the morbidity and mortality, 2 out of the 8 recorded cases having died as a direct result of the rupture of the cyst.

Acknowledgement.—I wish to thank Mr. W. W. Slack, under whose care this case was admitted, for permission to publish the case and for his useful criticism during the preparation of this paper.

CONGENITAL OESOPHAGO-BRONCHIAL FISTULA IN AN ADULT

By D. G. HILL

THORACIC UNIT, GUY'S HOSPITAL, LONDON

SUMMARY

A case of oesophago-bronchial fistula presenting in adult life and treated successfully by surgical excision is reported. Unusual features were severe halitosis and the downward direction of the fistula from the oesophagus to the lung.

FISTULOUS communication between the oesophagus and bronchi may be congenital, traumatic, inflammatory, or neoplastic. Fistulae which are muscular, epithelial lined, and clearly congenital, yet present in adult life, are rare and have been described only 29 times in the literature. This paper reports a further example of such a lesion (Belsey, 1966).

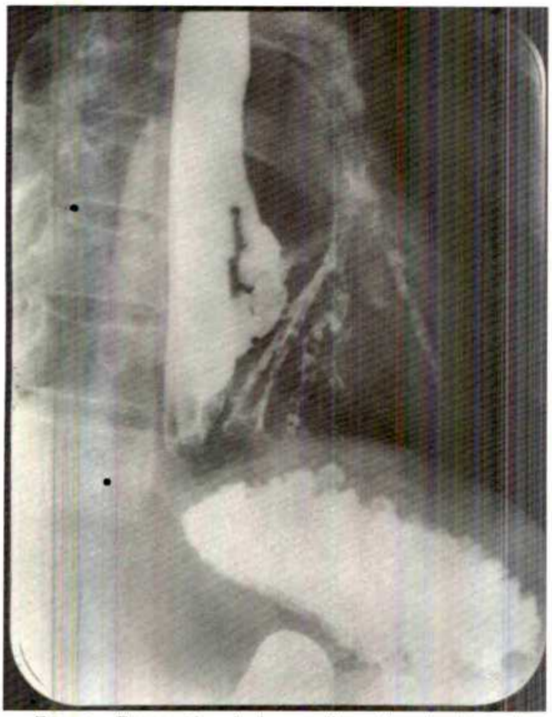

FIG. 1.—Preoperative barium-swallow film detailing the fistulous communication between the oesophagus and the left lung.

CASE REPORT

A 29-year-old Arab male presented to the Thoracic Unit, Guy's Hospital. He had a 16-year history of retrosternal burning pain after meals (especially with spicy meals), water brash, and postural oesophageal reflux, and a 3-year history of breathlessness, wheezing, and coughing up small particles of food on eating meals, especially related to spicy foods. He had had a tonsillectomy in Cairo 6 years previously with partial relief of symptoms for 3 years.

Severe halitosis was the only significant physical finding.

INVESTIGATIONS.—A chest radiograph was normal. A barium-swallow examination detailed an oesophago-bronchial fistula communicating with the posterior basal segment of the left lower lobe (*Fig.* 1). Oesophagoscopy showed free oesophageal mobility, and biopsy of the mouth of the fistula was reported as normal squamous epithelium. Bronchoscopy revealed a normal bronchosegmental anatomy and no sign of inflammation. Some barium was sucked out of the left common basal bronchus.

OPERATION.—At operation the fistula was located in the left inferior pulmonary ligament immediately below the pulmonary vein. There was no related fibrosis or inflammation. The fistula, which measured 1 cm. in diameter, led directly from the oesophagus in a downward direction into the posterior basal segment of the lower lobe. As the fistula entered the lung it became cystic. Segmental resection with excision of the fistula was performed, the oesophageal defect being closed by a double-suture line. The defect in the lung was oversewn.

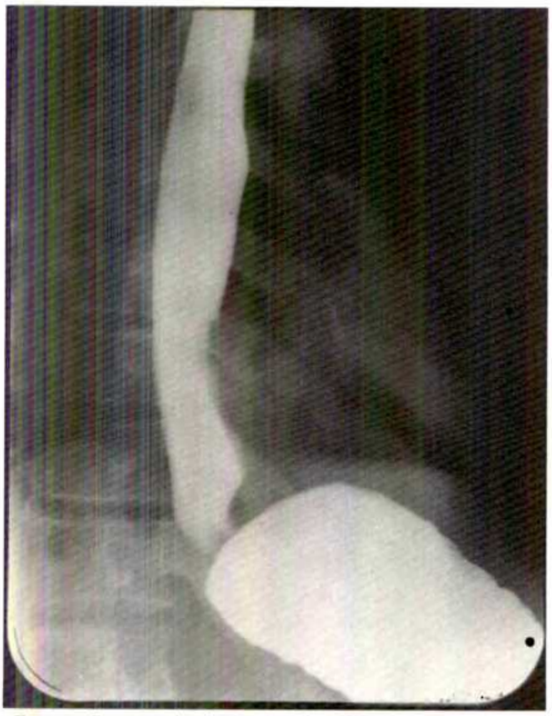

FIG. 2.—Postoperative barium-swallow film showing a normal oesophagus and no trace of the fistula.

Histological examination of the fistula revealed squamous epithelium with ciliated mucous glands embedded in the outer muscle layers.

The patient made an uneventful recovery. Postoperative barium swallow showed a normal oesophagus (*Fig.* 2).

There was a small encysted effusion at the left base which subsequently cleared (*Fig.* 3).

A year later at follow-up the patient had fully recovered with complete relief of symptoms.

DISCUSSION

Braimbridge and Keith (1965) classified 23 cases of congenital oesophago-bronchial fistulae collected from the literature. They divided the cases according to the manner in which they terminated at the respiratory end of the fistula. This is most commonly a single tract running to a lobar or segmental bronchus. However, the tract may first become cystic and then run into a bronchus (26 per cent) or occasionally it is in communication with a sequestrated segment of lung (17 per cent). The case reported here was clearly seen to be cystic at its bronchial end.

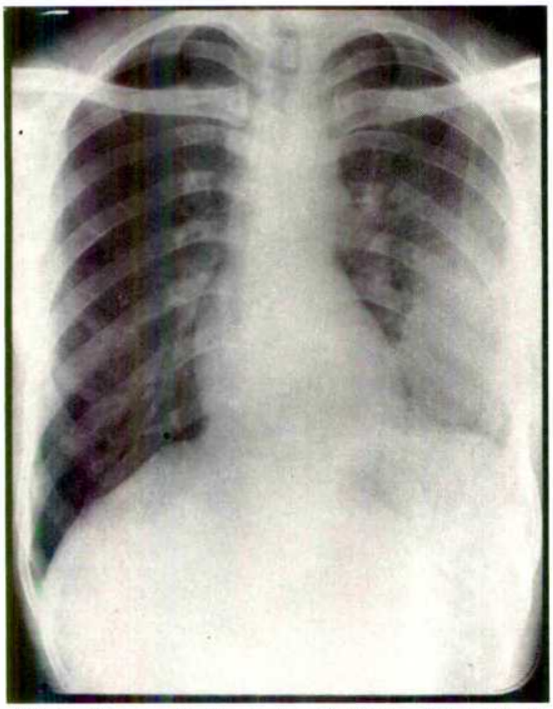

FIG. 3.—Postoperative chest radiograph showing the left pleural effusion.

Histology of the fistulous tract usually shows a muscular tube lined by either squamous or columnar epithelium. The congenital nature of the lesion is supported by the absence of inflammation.

Symptoms may begin in childhood but are often intermittent and not noticed. At presentation, usually in adulthood, chronic respiratory infections are the most frequent complaint. A cough is a consistent feature. Haemoptysis is not uncommon and may be massive (Kinley and Lang, 1969).

Alimentary symptoms are less common, but symptoms such as choking on swallowing or food particles found in the sputum can be diagnostic. Halitosis which was an important feature of the case presented here has not previously been noted.

The reason for the late onset of symptoms has been variously attributed to:—

1. A membrane in the tract which breaks down with age.
2. An operculum of mucosa which may intermittently cover the oesophageal end of the fistula and close it during swallowing.
3. The usual upward direction of the tract.

In the case reported late 'presentation' was due to incomplete investigations of the patient's symptoms previously. (He had had a tonsillectomy for the same symptoms 6 years before the diagnosis was made.) In fact he had had relevant symptoms for 16 years which may fit in with the downward direction of the fistula. The diagnosis is most convincingly made by barium swallow (65 per cent; Braimbridge and Keith, 1965). Bronchograms show the damage that has occurred in the lung but do not usually show the fistula. Endoscopy may reveal the orifice of the tract but this is usually only possible if the diagnosis has already been made (Le Roux and Williams, 1968).

Management is by resection of the fistulous tract alone or together with lobectomy, segmental resection, or pneumonectomy. There have been no operative deaths in any of the reported cases.

Acknowledgement.—I wish to thank Mr. A. K. Yates for his help in preparing this paper.

REVIEWS AND NOTICES OF BOOKS

The Shoulder and Neck. By JAMES E. BATEMAN, M.D., F.R.C.S., Toronto. 10½ × 7½ in. Pp. 615 + xiii. Illustrated. 1972. London: W. B. Saunders Co. Ltd. £13·85.

THIS is a most comprehensive work in which every facet of the surgery of the shoulder and neck is considered in a very practical manner.

This large volume is divided into seven sections. Section 1 deals with the basic sciences as related to the shoulder and neck. Developmental defects and anomalies are considered in some detail. The surgical anatomy of this large region is discussed and the principles of shoulder and neck function are considered.

In Section 2 the problems of investigation and diagnosis of various conditions and lesions are set forth.

Section 3 is devoted to a consideration of clinical syndromes. Degenerative tendinitis, ruptures of the rotator cuff, and frozen shoulder are well described.

Section 4, a large section, is dedicated to trauma of the neck and shoulder. There is a very comprehensive review of the common injuries to this region which occur in road accidents and in sports. As one would expect, nerve injuries are frequent and are described in some detail.

Section 5 deals with systemic disorders of the shoulder and neck; section 6 considers the many and varied tumours which are found in this part of the body, while in section 7 disability evaluation of the shoulder and neck come under review.

Throughout this volume the illustrations are of a high order, especially the line drawings which are original and convincing. The radiographs have been well chosen and are clear.

An excellent reference volume on an important region in the human body.

Spezielle pathologische Anatomie. Volume 2, Part 1: Oesophagus und Magen. By Professor Dr. WILHELM DOERR, Heidelberg, Professor Dr. GERHARD SEIFERT, Hamburg, and Professor Dr. ERWIN UEHLINGER, Zürich. 9¾ × 6½ in. Pp. 1077 + xvii. Illustrated. 1971. Berlin: Springer Verlag. DM.380.

IN the past continental textbooks on pathology showed a tendency to concentrate on the purely morphological aspects. Thus, pathology was usually identical with and was actually named pathological anatomy. In the present volume dealing with the systemic pathology of the oesophagus and the stomach the authors have broken the strings that traditionally bound them and have included a good deal of functional pathology. As they have not given up an inch of their morphological territory this means that the actual text runs to 850 pages. Another trend in this book is to include material that is of interest to the clinician—gastro-enterologist or abdominal surgeon—so that he will hardly ever look in vain for even the most specialized details. This gigantic handbook is all that it should be: a masterly review of the pertinent literature, blended with personal observation, illustrated with good photographs, and spiced with useful diagrams. All aspects of the subject are extensively covered, as can be easily proved by randomized checks on obscure or rare conditions. Of course, the book is primarily of importance to him for whom it was written: the pathologist; but surgeons engaged in research will certainly do well to consult it. The first section on the sequelae of gastric operation has a wider appeal and could fruitfully be consulted by the practising surgeon. The final 170 pages comprise an impressive list of references, extending from the dawn of pathology to 1969. It is a pity that the authors, who obviously have read a great many of these articles, have not annotated this bibliography. It might have been helpful in selecting articles for further reading because reading them all would probably take a lifetime.

Acute Cholecystitis. By CLARENCE J. SCHEIN, M.D., New York. 10 × 7 in. Pp. 309 + xv, with 179 illustrations. 1972. New York: Harper & Row, Publishers, Inc. $17.50.

A WHOLE book devoted to the subject of acute cholecystitis—is this possible? Yes, because this is simply a phase of the obstruction of the cystic duct.

This book covers the whole pathology of cholecystitis and includes the aetiology, diagnosis, treatment, and results of treatment.

The first chapter discusses the historical background to the condition, and presents biographical sketches of the surgeons of the past who have written about acute cholecystitis. It is pleasing to see photographs of Lord Moynihan and Rutherford Morrison as pioneers of the English school.

Cholecystectomy is the treatment of choice in this condition, and the author has discussed in considerable detail the complications which may occur following surgical intervention. Stones in the cystic duct remnant are common.

There is a most extensive list of some 629 references at the end of the book.

Bacterial Infections. Changes in their Causative Agents. Trends and Possible Basis. Edited by M. FINLAND, W. MARGET, and K. BARTMANN. 10 × 7 in. Pp. 231 + viii, with 53 illustrations. 1971. Berlin: Springer Verlag. DM.48.

THIS book comprises the papers read at the third Bayer symposium. The first symposium was devoted to problems of immunology, and the second to catecholamines.

The twenty-two contributors come from America, Great Britain, Germany, Sweden, France, and Switzerland. Every facet of this important subject is discussed at length.

Infections in hospital wards, in operating theatres, and elsewhere in hospital buildings are tabulated and comparisons are made between different groups of hospitals. The changing pattern of infecting organisms is described in some detail.

Sensitivity to various types of antibiotics is set out in an interesting manner.

This book should be of interest to surgeons, as the biological, epidemiological, and therapeutic points of view are portrayed in a very practical way.

This is an important reference volume on an important subject.

Resistance to Trauma. By Zdenek Hruza, M.D., Ph.D., Sc.D., New York. 9 × 6 in. Pp. 97 + xiv, with 13 illustrations. 1972. Springfield, Ill.: Charles C. Thomas. $7.

This monograph written by a pathologist seeks to investigate the important problems of shock and trauma. By the use of animal experiments the effects of repeated trauma on the various organs of the body have been studied. Therapeutic approaches, such as adrenergic blockage, treatment with novocaine, depot epinephrine, and norepinephrine, and increase of saturation of the portal blood with oxygen by insufflation of oxygen into the bowels are all critically reviewed.

The author has made a complete review of the literature on trauma and has included a very extensive bibliography at the end of the book.

Neonatal Emergencies and Other Problems. By John Black, M.D., F.R.C.P., Sheffield. 8½ × 5½ in. Pp. 282 + v. 1972. London: The Butterworth Group. £3·75.

This is an important book for the clinician, for it sets out the facts and figures concerning the day-to-day care of the newborn infant. Birth trauma is considered at length, and the list of complications which may result from forceps delivery is a long one. Such problems as maternal diabetes and the pre-diabetic state are dealt with in a very comprehensive way.

An interesting chapter on maternal addiction to alcohol is impressive. Another very practical chapter is devoted to the difficult problem of talking to parents—the author is at his best here.

There are some very useful appendixes at the end of the book.

This book will appeal to house-surgeons and practitioners alike, while senior students and nurses will find it a useful reference volume.

La Chimiothérapie regionale des Cancers de l'Appareil digestif. By P. Kissel, M. Bessot, A. Duprez, and G. Mauuary, Nancy. 9½ × 6 in. Pp. 216 + x, with 15 illustrations. 1971. Paris: Masson et Cie, Editeurs. 46F.

This most fascinating monograph deals with chemotherapy of gastro-intestinal malignancy. A group of scientists of various disciplines has been collaborating in Nancy for more than 10 years. They have borrowed widely from other workers but have also added many original ideas and techniques of their own. The quintessence of their method is regional perfusion after synchronization of the cell kynetics. When the proliferative cycle is synchronous all the cells will be affected by a drug active in a specific phase as soon as this phase is reached. In this way a maximum effect can be obtained with relatively small amounts of antimitotic substance. To prevent a deleterious effect on the remainder of the body chemotherapy is given through the nutrient artery of the tumour.

The book is made up of five chapters. The first gives an account of basic cellular physiology, explaining DNA metabolism and how autoradiography is derived from it. The second chapter summarizes the currently used antimitotics and their mode of action. The introductory part is closed by a third chapter on how to regionalize chemotherapy, discussing the various routes that can be used and the complications to be expected. In the second part of the book the knowledge acquired in the introduction is applied to three specific tumours: carcinomas of the liver, the stomach, and the rectum. As wide experience has already been gained in Nancy this section, giving overall results and illustrative single case histories, is most important. For anyone actually engaged in using this sort of therapy this book is obviously compulsory. It seems, however, to have a much wider appeal, for it can be unreservedly recommended to beginners who want a lucid and authoritative introduction to this rapidly expanding field that seems so full of promise.

Modern Trends in Orthopaedics—6. Edited by A. Graham Apley, M.B., B.S., F.R.C.S., Pyrford, Surrey. 8½ × 5½ in. Pp. 273 + x. Illustrated. 1972. London: The Butterworth Group. £7·50.

Orthopaedic surgery covers an ever-expanding branch of surgery and these 'Modern Trends' volumes are invaluable to the postgraduate who is studying for higher degrees or diplomas in surgery. This series is also of real use to the young orthopaedic surgeon who wants to keep abreast of this specialty.

The range of subjects covered in this book is very wide. A comparison of postgraduate training in Great Britain and the United States of America is made. Total hip replacement and total replacement of the elbow-joint are discussed at length. Other important chapters deal with coxa plana, arthroplasty of the knee-joint, and epidurography in a very practical way.

This book is a great credit to the 'Modern Trends' series.

The Elephant Man. By Ashley Montagu, Princeton, New Jersey. 8¾ × 5½ in. Pp. 140 + x, with 28 illustrations. 1972. London: Allison & Busby. £2·10.

This book, written by a well-known American anatomist and anthropologist, concerns a very bizarre man called by Sir Frederick Treeves the 'Elephant Man'.

The book is dedicated to the memory of Charles S. Sonntag, an anatomist who worked at University College in London.

Although much has been written about John Merrick, the Elephant Man, by Sir Frederick Treeves and others, never before has such a complete account been presented. Ashley Montagu, an author of some forty books, always showed a great interest in this patient of Treeves. The author also gives a very interesting short account of the life of Sir Frederick Treeves.

This book is a mixture of a detective story and a warm portrait of an apparently ugly figure who is likely to capture the affection of every reader.

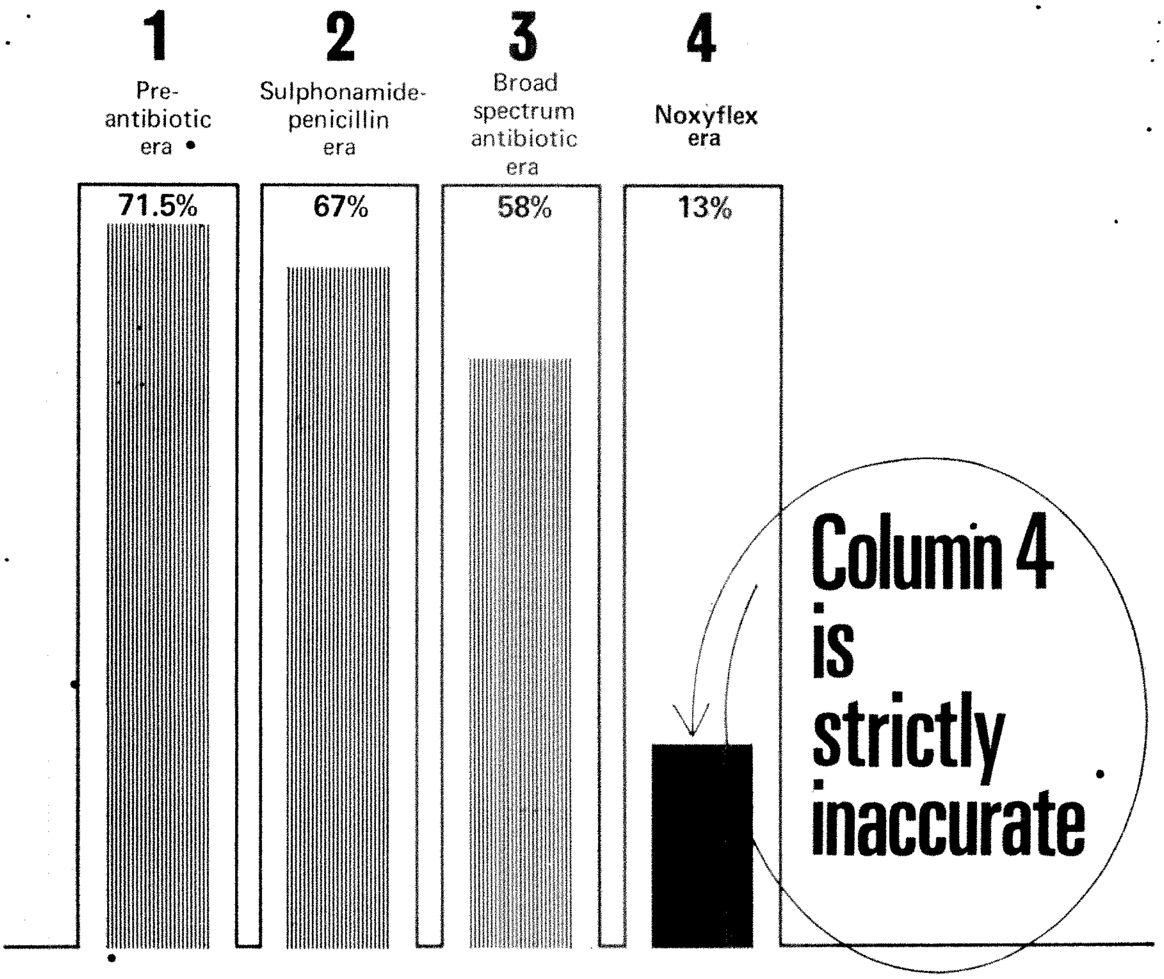
A book which will interest doctors, students, and nurses, as well as the lay public.

Handbuch der medizinischen Radiologie. Volume 5, Part 4. Edited by L. Diethelm, Mainz. 10½ × 7½ in. Pp. 824 + xx. Illustrated. 1971. Berlin: Springer Verlag. No price given.

This volume of the 'Encyclopaedia of Medical Radiology' deals almost entirely with juvenile osteochondritis. The disease process is discussed and illustrated in relation to virtually every bone in the body but of course the hip-joint gets more attention than the rest.

A section on congenital coxa vara is included. This mammoth work has been produced by a single author and contains a vast number of up-to-date references, most of these relating to the German rather than the English literature. Undoubtedly this volume will become a standard reference book for this particular condition.

The graph below compares mortality rates due to faecal peritonitis, era by era.
It is not pedantically accurate because its sources differ. But the point is fairly made.



Why inaccurate? Because column 4 refers to 23 cases of faecal peritonitis which were treated successfully with Noxyflex. But the *3 deaths which occurred were due to causes other than peritonitis - as post-mortem revealed. **The mortality rate due to peritonitis can therefore be regarded as zero.**

* The whole graph, and the causes of the deaths referred to are the subject of the new Noxyflex folder "Why three deaths?" You will receive at least one copy!

..hen bacterial contamination of the peritoneum is diagnosed or suspected: Noxyflex

OUTLINE OF FRACTURES, INCLUDING JOINT INJURIES

J. CRAWFORD ADAMS

1972 *Sixth Edition 320 pages 267 illustrations*

£2·25

'Within the limits implied by its title this book is probably the best of its kind yet published. All the common bone injuries, and their complications, are here described, and all the usual methods of managing them are enumerated.'—*Lancet*

'A work which is now firmly established as one of the most reliable books upon which medical students, house officers and practitioners have come to depend.'—*Proceedings of the Royal Society of Medicine*

'The student of today is indeed fortunate to have the work of an author who can, with a minimum of words and the painstaking collection of illustrations, make the difficult subject of fractures easy to read and understand. The excellent references and bibliography greatly enhance the value of the book for those who propose to study further this important subject.'—*Journal of the College of General Practitioners*

THE SCIENTIFIC BASIS OF SURGERY

Edited by W. T. IRVINE

1972 *Second Edition 680 pages 173 illustrations*

£9·50

'This is a book for those seeking up-to-date authoritative information on the scientific problems underlying day-to-day surgical practice. It will prove of immense value to postgraduate students, to men about to undertake research projects, and to many practising surgeons, particularly those with teaching responsibilities. Its scope must make this an exciting and stimulating book for any young surgeon; and the amount of information it contains and its value as a guide to the original literature will make it an essential reference for all serious students of surgery. Professor Irvine and his collaborators are to be congratulated on this outstanding volume.'—*Lancet*

FUNDAMENTAL TECHNIQUES OF PLASTIC SURGERY AND THEIR SURGICAL APPLICATIONS

IAN A. McGREGOR

1972 *Fifth Edition 312 pages 180 illustrations*

£4·00

'Mr McGregor is to be congratulated upon his breadth of outlook and his industry in producing this edition. We recommend it to all surgeons who have occasion to treat injuries or deformities resulting from ablative surgery. It can hardly be possible to obtain a more concise and reasonably comprehensive introduction to plastic surgery.'—*British Journal of Plastic Surgery*

no fear
no infection
no pain

with a Porges golden balloon catheter

No pain : it has an impeccably smooth surface and the balloon when deflated leaves no protrusion. This allows easy insertion and withdrawal.

No fear : the patient feels completely reassured. He will be utterly relaxed during catheterization. A large surface for vesical support is obtained through even inflation of the balloon, ensured by reinforcing ribs.

No infection : the incorporation of active bacteriostatic compounds into the latex prevents any urinary tract infection.

Our research department has devoted all its efforts to the production of catheters which satisfy all clinical requirements :

The Porges balloon catheter
the golden catheter
created for the patient's
safety and comfort.

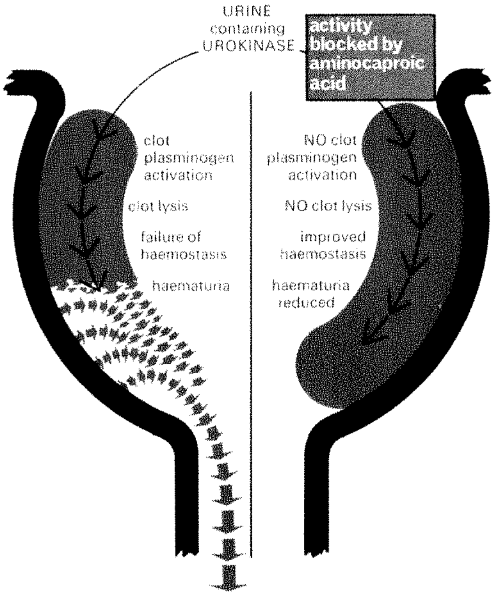
The
mechanism of
post-prostatectomy bleeding
and
EPSIKAPRON®
control



Epsikapron (aminocaproic acid) is rapidly excreted in the urine in high concentration ; there it inhibits urokinase, the fibrinolytic enzyme in urine. With the haemorrhage-sustaining property of urine blocked, the haemostatic coagulum becomes adequate, and blood loss is diminished substantially.

Epsikapron makes your prostatectomy patient's post-operative course smoother by diminishing :

the need for post-operative blood transfusion
clot retention
catheterization
the risk of infection
the period of hospitalization

Presentation

EDITORIAL NOTICES

EDITORIAL COMMUNICATIONS should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol, BS8 1EX.*

Original Articles are invited, and should be sent, whenever possible, to a member of the Editorial Committee: they are accepted with the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

REPRINTS can be supplied at a reduced price if authors indicate their requirements at the time that proofs are returned. The following scale will be helpful as a guide to the cost; 50 copies are suggested as a minimum number.

NO. OF PAGES	NUMBER REQUIRED							
	50	100	150	200	250	300	400	500
2	£2·83	£3·70	£4·27	£5·07	£5·69	£6·32	£7·74	£8·99

An extra 16p per 300 pages will be charged for reprints sent to outside the United Kingdom.

An additional charge will be made for reprints containing coloured illustrations, depending upon the amount of extra work involved.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol, BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 58. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

BACK NUMBERS.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

ADVERTISEMENTS.—All communications should be addressed to *H. S. Janes & Partners (Publications) Ltd., St. Martin's House,* 159 *Clapham High Street, London, S.W.*4 7SU 01 622 9225.

INSTRUCTIONS TO AUTHORS

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

TABLES AND ILLUSTRATIONS.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too, should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

REFERENCES.—The arrangement is based on the Harvard System.

In this system the name of the author and the date of the publications are given in the text; the list of authors quoted is put at the end of the article in alphabetical order. Each reference in the list should give, in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volume (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has written more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, the place of publication should be stated and the publisher's name. The names of collaborating authors should be given in full on the first occasion, but in later citations the words "and others" should follow the first name. Abbreviations for journals should be those adopted in the "WORLD LIST OF SCIENTIFIC PERIODICALS" (1963).

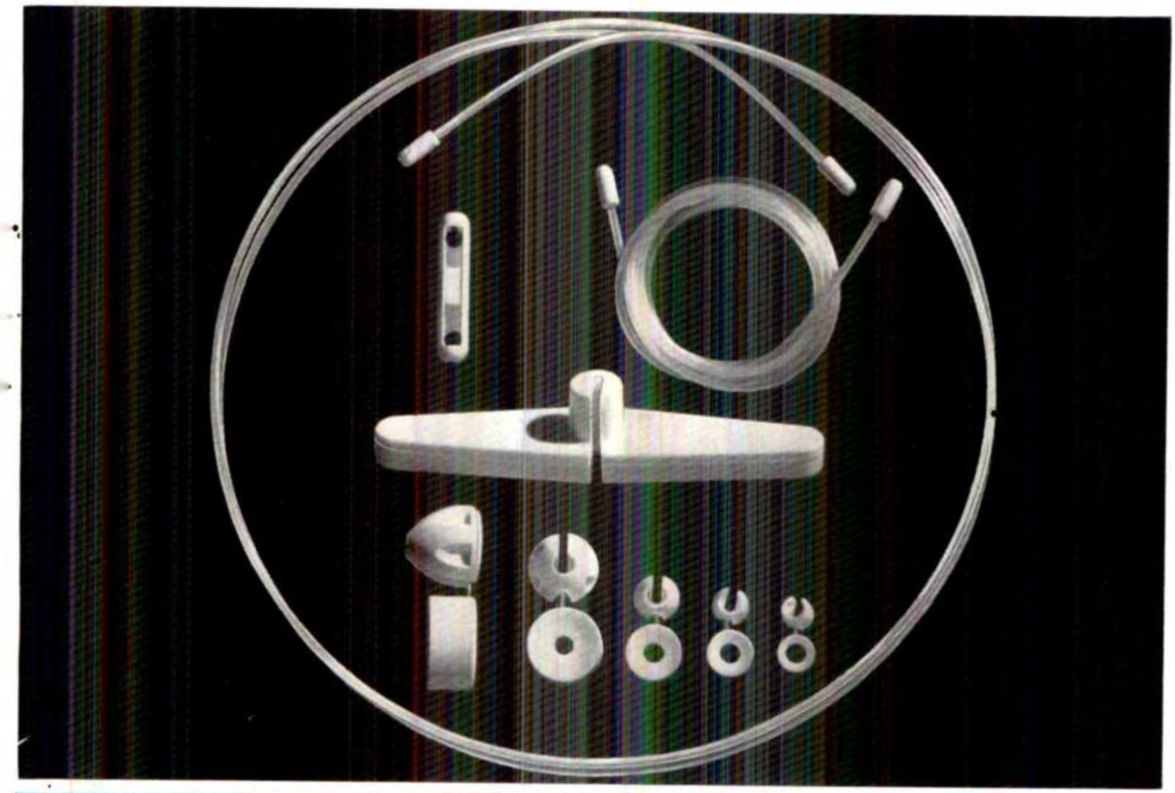
Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names.

Armour Vein Stripper

Sterile, disposable, non-toxic and pyrogen-free

Eliminates time-consuming preparation and cleaning

Sterilised by irradiation



Nylon Cable

Has optimum handling quality.

Every end stop individually tested for firmness of attachment.

Breaking load of cable in excess of 150 lb.

Nylon Olives

Snap fit for convenience of assembly.

Clean, well-defined cutting edge.

Hole without edge access prevents cable detachment.

Nylon Coupler and Draw Handle

Smooth, compact, coupling, ensures security of union.

Light, strong, well shaped.

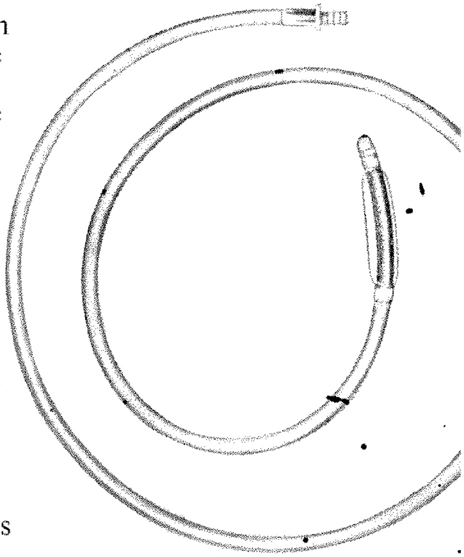
Our research is done in close consultation with the medical profession, and as a result we have devised equipment and test procedures where none previously existed. One such is the Portex Flex Test for Intravenous cannulae.

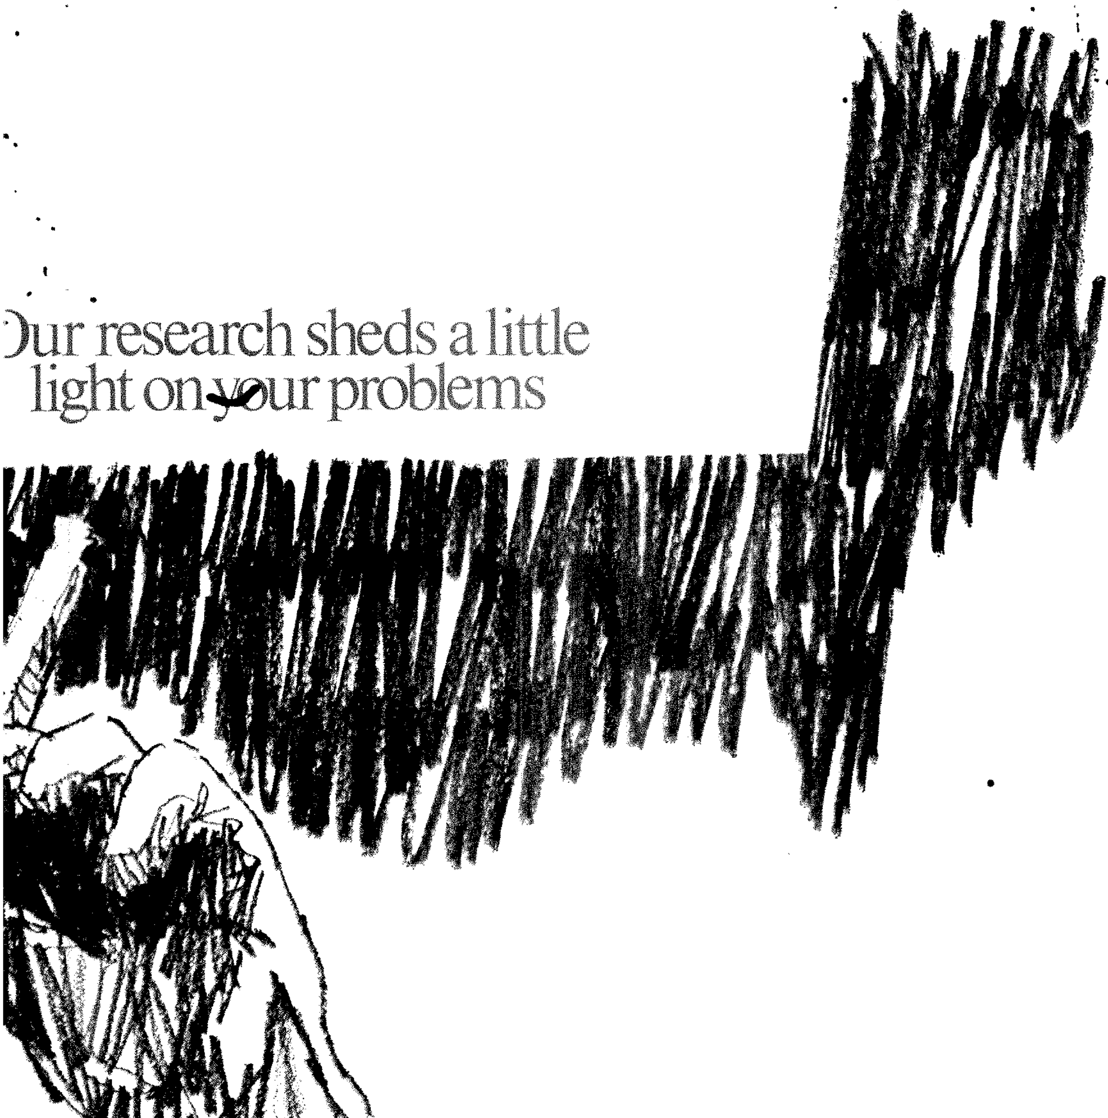
Our new product development programme has made possible significant advances in medical techniques. Like the Atrial Cannula. Like the Salpekar Tracheostomy Tube. Like the Cholangiogram Cannula. And more.

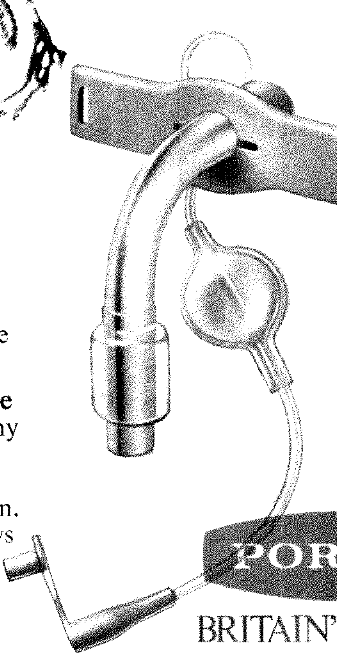
We are also in the forefront of the development of disposable products. This has entailed still further expertise and leadership in sterility procedures, biocompatibility testing, raw materials standards, identity and containment of microbial contaminant levels.

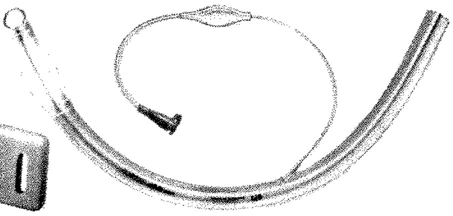
We like to feel that our research supports your search for greater medical advances.



)ur research sheds a little
light on your problems







ophageal Stethoscope
This is a new product which
ovides a simple, yet highly
icient method of monitoring
art sounds. It is particularly
eful during paediatric and
urosurgical procedures.
vailable in three sizes, all double
apped and sterile.

ue Line Tracheostomy Tube
The new Portex tracheostomy
be has an extra smooth
n-irritant finish designed to
ow easier suction catheterisation.
e strong inert floppy cuff allows
wer inflation pressures.
ch tube is supplied with a one
y valve and its own spool
neck tapes.

Cuffed Blue Line Endotracheal Tube Designed with a new thin wall to give up to ½ mm larger lumen than before and with even better slip properties. The cuff is inflated symmetrically via the airline which is incorporated into the wall without reduction of lumen.

The most important pipe cleaner in the world...

Eschmann Embolectomy Catheter

- ✳ Pure latex balloon—soft when inflated to conform to arterial irregularities
- ✳ X-ray opaque — so you can see what it's doing
- ✳ Graduated along the shaft — so you can see where it is
- ✳ Colour coded — to help find the right size quickly
- ✳ Sterile—in rigid protective pack
- ✳ Made with care and tested with concern

It all adds up to the most important pipe cleaner in the world.

Manufactured by

ESCHMANN

Shoreham-by-Sea, Sussex

Available from established surgical dealers.

360° VISION

BARD* SANI-SCOPE

A clear plastic, disposable anoscope with removable obturator that provides 360° inspection without rotation. This instrument allows more relaxed examination as the patient experiences less thermal discomfort than with a metal anoscope. The SANI-SCOPE is just one of a new range of diagnostic instruments now available from Bard.
For further information on these products please contact Bard at the address below.

Why Dexon*?

1. Easy to handle–similar to silk or linen thread
2. Packed dry–convenient to use
3. High tensile strength–excellent wound support
4. Smaller gauges needed for comparable strength compared with gut
5. Braided construction–secure knots–more security
6. Predictable absorption even in contaminated areas
7. Minimal tissue reaction and inflammatory response
8. Improved patient comfort
9. Permits undisturbed wound healing
10. Less painful wounds
11. Shorter hospitalization
12. Improved cosmetic results especially with subcuticular stitches
13. Is there when it is needed, but has gone when it is not
14. Multi-uses means greater economy
15. May be removed as usual when used for skin sutures but may be left to absorb if preferred–e.g. paediatric surgery, under orthopaedic plaster casts, episiotomy repairs, circumcisions, etc.
16. Simplified stock holding, laying up for operations, nurse training
17. It is supplied on the best suture needles made

Why not?

1. The braided construction may mean an initial difficulty in tying knots
2. A slight increase in tissue-drag may be experienced. Can be improved by wetting
3. Absorption of blood and other body fluids may make Dexon more difficult to see
4. Suture for suture it appears to be more expensive than other materials –cost in use is probably less
5. It is different and you may need to especially ask for it

Dexon* the suture that supersedes catgut

OP-SITE BARRIER

TRADEMARK

The most effective adhesive drape

Unlike other sterile adhesive drapes, Op-site can breathe.

Which puts it at something of a premium. Because it allows a continual exchange of gases: oxygen to the skin, water vapour away from it.

There's no maceration of tissue and no perspiration build up to loosen the adhesive. Just total conformability and strict adhesion throughout.

Because of this, Op-site may be sutured through and left to protect the skin till the stitches are removed.

Post-op protection makes sense. Use Op-site.

SPECTROLITE

THE SUPERB RANGE OF LIGHTWEIGHT, THORACIC RETRACTORS!

The Thackray Spectrolite range is a new concept in Thoracic Retractors and Rib Spreaders. The various models are precision made in lightweight alloy combining optimum strength with ease of handling. The blades and arms are finished in non-glare black, the gear track in non-glare satinised alloy for minimum optical distraction and strain in the theatre.

Send for illustrated literature of the full range.

ORIGINAL PAPERS

METABOLISM AFTER INJURY. 1: EFFECTS OF SEVERITY, NUTRITION, AND ENVIRONMENTAL TEMPERATURE ON PROTEIN POTASSIUM, ZINC, AND CREATINE

BY D. P. CUTHBERTSON, G. S. FELL, CATHERINE M. SMITH, AND W. J. TILSTONE

UNIVERSITY DEPARTMENT OF PATHOLOGICAL BIOCHEMISTRY, ROYAL INFIRMARY, GLASGOW

SUMMARY

The effect of an environmental temperature of 28–30° C. and a relative humidity of 35–45 per cent on the protein metabolic response to injury of one or more major long bones of the lower limbs has been studied in 29 male patients and 28 similar controls housed at 20–22° C. The metabolic response was reduced at the higher temperature compared with the controls, the more severely injured showed a greater metabolic response than the less severely injured, and the ameliorating influence of environmental temperature was more noticeable in the former. The metabolic response seems to be principally one of catabolism of muscle, with increased urinary excretions of potassium, creatine, and zinc in the urine correlating well with those of nitrogen at 20° C. but not at 30° C. The response (i.e., catabolism of muscle) was not affected by post-injury diet at 20° C. ambient temperature. There was a reduction in the disturbance of the plasma proteins.

In general, the patients tolerated the warm drier conditions. Owing to the intrinsic difficulty in assessing minor changes in bone healing it was not possible to assess what, if any, beneficial change occurred in the fracture site. From our experimental observations on the rat and the work of others on burned patients the reduction in heat production at the higher ambient temperature is accompanied by an enhanced rate of healing of surface wounds.

THE metabolic response to injury is both local and general. It is with the latter in its post-shock manifestations following moderate to severe physical injury to the limbs of man that this report is concerned, and, in particular, with the effect on this response of raising the environmental temperature to the zone of thermoneutrality for clothed man (28–30° C.). This topic has been of considerable interest to those working in the field of metabolic response to trauma (Campbell and Cuthbertson, 1967; Miksche and Caldwell, 1967; Barr, Birke, Liljedahl, and Plantin, 1968; Cuthbertson, Smith, and Tilstone, 1968; Caldwell, 1970; Davies and Liljedahl, 1970; Tilstone and Cuthbertson, 1970; Spivey and Johnston, 1972).

The essential elements in the generalized response to injury were described by one of us (Cuthbertson, 1930, 1932, 1936, 1942) and extended by Wilkinson, Billing, Nagy, and Stewart (1949, 1950) and Moore and Ball (1952) among others. The complex series of reactions to various forms of injury has as its main components over the first 10–14 days after injury increased net protein catabolism and parallel increases in heat loss and oxygen consumption. There are also characteristic changes in plasma-protein levels (Owen, 1967; Cuthbertson and Tilstone, 1969).

The extent of the metabolic response seems to depend on the nature and severity of the injury, being slight for uncomplicated surgery, greater for major skeletal injuries, and considerable in sepsis and major burns (Kinney, Long, and Duke, 1970).

The present report is concerned with our observations on the effect of severity of injury and environmental temperature on the magnitude of the metabolic response and with observations on the major source of the nitrogen which is lost in urine.

MATERIALS AND METHODS

Patients.—Patients were all males ranging in age from adolescence to 70 years. They were either victims of accidentally sustained injuries of moderate to severe extent involving one or more long bones of the lower limbs or were patients undergoing elective arthroplasties of the hip or arthrodeses of the knee- or ankle-joint.

Environmental Control.—The patients were housed in single-bed cubicles which had partition walls of double-sheet aluminium and double glazing. A two-way cupboard allowed urine collections and food residues to be removed without opening the door of the room. Each cubicle had a Rootes Tempair 1½ h.p. water-cooled air-conditioning unit (W. Kemp, Glasgow) with a cooling capacity of 15,000 B.Th.U. per hour, and a 3-kV.A. heating unit with an air flow of 400 c. ft. per minute. Air passing through the unit was filtered in a washable polyurethane filter. Normally the dehumidification unit was not used since this cooled the air and produced rapid temperature drops if the thermostat was 'off' while the humidostat was 'on'. A 1-kV.A. convector heater was also used in winter. This apparatus could maintain a temperature of 29–30° C. and relative humidity of 35–45 per cent in all normal external environmental conditions. Opening the door for access did not cause a major temperature fall (*Fig.* 1).

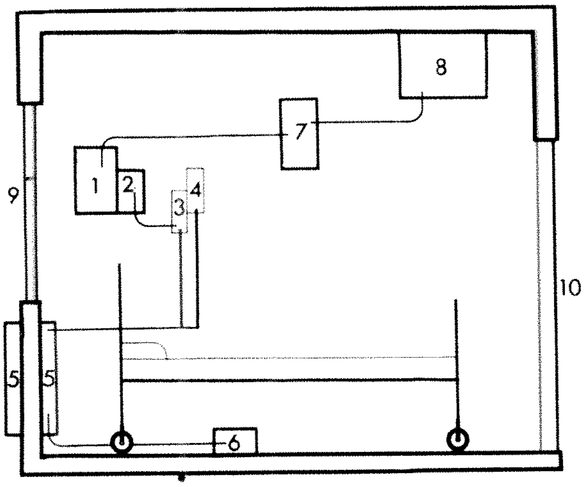

FIG. 1.—Linked thermal and humidity control of air changes in single-bed cubicle. 1–2, Mains junction box and on/off switches. 3, Thermostat. 4, Humidistat. 5, Rootes Tempair 1½ h.p. unit. 6, Water pump. 7, Thermostat and fan. 8, 1-kV.A. convector heater. 9, Cubicle window. 10, Cubicle door.

Experimental Protocol.—Twenty-nine patients were studied with the cubicles maintained at 28–30° C. and 28 with the cubicles maintained at 20–22° C.—the normal range of ward temperature. Subsequently only the figures 30 and 20° C. will be used as most of the cases fell into these temperature levels. The metabolic investigations began as soon as the initial shock phase was over and usually was within 24 hours of injury. Informed consent was obtained from all the patients. A few cases could not tolerate the warmer conditions and were removed from further study. The pattern of the diets presented was based on the patients' normal home intake which had been elicited by questioning, except that a protein intake (76 per cent of animal origin) which contributed not less than 13 per cent of the total calorie intake was always attempted.

Observations were made daily on various parameters of protein and tissue catabolism. Results for all of these are not available for all the patients. In general, results have been averaged for the following four periods: the first 4 days after injury (and we usually did not have results for the first day) and the three subsequent 3-day periods (but some patients were discharged before the end of the last of these 3-day periods).

Excess urine nitrogen was calculated by subtracting each day's food nitrogen intake from the total urinary nitrogen excretion from 08.00 on that day to 07.55 on the next morning. Faecal nitrogen was not measured since it is not indicative of endogenous protein metabolism and Cuthbertson (1936) has shown it to be a fairly constant 6 per cent of intake at all stages after injury in man, and Campbell and Cuthbertson (1967) also found it to be unaffected by trauma in the rat.

Food Intake.—Net food intake was obtained by weighing food presented to the patient and subtracting all the residues. Intake of nitrogen and energy was calculated from the tables of McCance and Widdowson (1960), with occasional checks of nitrogen by analysing one-quarter of total homogenized diets.

Chemical Methods.—Nitrogen was estimated by a semi-mechanized Kjeldahl technique based on that described by Fleck (1967). Zinc was estimated by atomic absorption spectrophotometry using a Pye Unicam SP90, potassium by flame photometry, and creatine by a fluorescent technique using the Auto Analyzer (Tilstone and Fell, 1971). The urine was preserved by providing 5 ml. of 10 per cent thymol in isopropanol.

Statistical Analysis.—Statistical analysis of results was performed on an IBM 1130 computer using standard programmes for analysis of variance, Student's t-test, correlation coefficients, and linear regressions with one or more independent variables.

RESULTS

1. Patients.—Retrospective analysis shows that the two groups of patients, that is those at 20° C. and those at 30° C., were not significantly different in age (t-test, $P > 0{\cdot}05$), extent of traumatic fever (t-test, $P > 0{\cdot}05$), and perhaps also degree of trauma. The extent of traumatic fever was measured by scoring the number of days within the 13-day period on which oral temperature was 37·2–37·7° C., 37·8–38·2° C., or over 38·3° C. at least once a day, the scoring being 1, 2, and 3 points respectively for these zones. The severity of trauma was assessed in two ways: the first was dependent upon the amount of blood replacement which was necessary and the other on the extent of the trauma as defined on an arbitrary scale ranging from 1 to 7, for example, fracture of both femora and both tibiae and fibulae, 7; fracture of one femur and the tibia and fibula of the other leg with deep lacerations including severed tendons of the arm, 5; fracture of both tibiae and fibulae with lacerations and contusions, 4; comminuted fracture of the femur, 3; fracture of the neck of the femur, 2·5; fracture of the tibia and fibula, 2; Pott's fracture, 1; Charnley arthroplasty of one hip-joint, 5; triple arthrodesis of the ankle-joint, 2. On these two bases of assessment the two groups did not appear to be significantly different (t-test, $P > 0{\cdot}05$). The results are shown in *Table I*. A subsequent division in each group into moderate to severe injury on the one hand (+), and less severe on the other (−), was made on the basis of 2·5 and above for the former and below 2·5 for the latter. Only in 3 cases of the latter group was some blood necessary.

Table I.—Comparison of Age, Extent of Traumatic Fever, and Severity of Injury in the Two Groups of Patients

Ambient Temperature (° C.)		Age	Fever Rating	Trauma Rating	
				Score	Pints of Blood
20	Mean (*N*) S.E.M.	41 (28) 3·0	3·0 (21) 1·0	2·7 (28) 0·3	1·5 (12) 0·5
30	Mean (*N*) S.E.M.	37 (29) 3·0	3·0 (26) 0·4	2·6 (29) 0·2	1·0 (9) 0·3

2. Intake of Energy and Nitrogen in Food.—Taking all the patients at 20° C. as one group and all those at 30° C. as the other, their food energy and food nitrogen were compared on the basis of the means for each successive period of study, that is, over the first 4 days, then the subsequent three 3-day periods. A comparison was also made on the basis of the means of all periods taken together. As can be seen from *Table II* there was no significant difference between the two groups at any time in respect of energy or protein intake. It is of interest that intake was not reduced by the warmer atmosphere.

Table II.—Intake of Energy and Nitrogen

Ambient Temperature (° C.)	Intake		Period				
			Overall	1	2	3	4
20	Energy (MJ. per day)	Mean (*N*) S.E.M.	9·5 (97) 0·3	8·0 (23) 0·5	9·5 (25) 0·5	10·0 (25) 0·5	10·2 (24) 0·6

* Differs significantly from severe injury group, $P < 0{\cdot}05$.
† Differs significantly from 20° C. group, $P < 0{\cdot}05$.
‡ Differs significantly from 20° C. group, $P < 0{\cdot}01$.

3. Excess Urine Nitrogen Excretion.—Trauma has been shown not to affect appreciably the digestibility of protein and thus the extent of catabolism of endogenous protein can be measured by following excess nitrogen excreted in urine, that is, the difference between urine nitrogen and food nitrogen. As well as by analysis in temperature groups as described above, the results for excess nitrogen were also subdivided according to the severity of trauma, as scored on the arbitrary scale. Within this subdivision the excess urine nitrogen excretion for the patients at each temperature was compared in each period, that is, those more severely injured and housed at 20° C. were compared with those less severely injured and kept at the same temperature, the comparison being made separately for periods 1, 2, 3, and 4; and similarly for the patients housed at 30° C. Comparisons were also made on the basis of equivalent injury but different temperature, that is, more severely injured at 20° C. against more severely injured at 30° C., and similarly for the less severely injured. These comparisons were made both for the means of the individual periods and for all the periods taken together.

The results (*Table III*) show that at 20° C. the more severely injured patients had a significantly higher excretion of excess nitrogen in the third and fourth periods ($P < 0{\cdot}01$) than did the less severely injured, but at 30° C. the more severely injured did not have such a significantly increased nitrogen excretion at any time. The less severely injured at 20° C. did not have a significantly greater excess nitrogen excretion than those at 30° C., the average being 1·04 g. per day higher at 20° C. but with $t = 0·62$. Taking the more severely injured there was a marginally significant difference in period 2 ($P = 0·05$) and overall the average difference was 3·01 g. per day. When all the degrees of injury are taken together then the difference between the two temperatures is more statistically significant, probably due to the greater number of degrees of freedom. Analysis shows that, taking all the periods together, the patients at 30° C. have a very significant reduction in their nitrogen excretion ($P < 0·01$), which is probably mainly in the early stages of the response, with the first period being significantly reduced at $P < 0·05$.

Table IV.—URINARY EXCRETION OF NITROGEN, ZINC, AND CREATINE

4. Excretion of Products of Tissue Protein Catabolism.—Excretion of total urinary nitrogen was never significantly different between the two groups no matter how the comparison was made (*Table IV*). It may be felt that if the excess nitrogen is significantly different between the two groups, then food nitrogen and/or urine nitrogen should differ significantly also. Food nitrogen did not differ (*see above*), and the large variance of urine nitrogen excretion, being the sum of the variance due to intake-associated factors and the variance due to endogenous protein catabolism, placed the average difference found in urine nitrogen excretion well below the level required for a statistically significant difference.

We wished to test the extent to which tissue catabolism, particularly muscle, might be responsible for the response of increased net nitrogen as had been shown in the rat (Cuthbertson, McGirr, and Robertson, 1939). To this end the urinary excretions of potassium, creatine, and zinc were examined.

Potassium is primarily an intracellular ion and it is well established that total-body potassium correlates well with the lean body mass.

Cell potassium may at times be quickly depleted following trauma (Moore and Ball, 1952). In the fractured rat an increased urinary excretion of potassium was found, reaching a peak some 3 days after injury, and the loss of potassium from muscle may be greater than for nitrogen over the first few days (Cuthbertson and others, 1939). Wilkinson and others (1950) and Le Quesne (1967) have described the increased excretion of potassium after abdominal injuries and the former showed that it is greater than that attributable to reduced food intake after partial gastrectomy. Moore and Ball (1952) have further delineated the situation, showing that in burns the potassium loss may last for only 2–4 days. They have also drawn attention to the normal early postoperative response whereby there is a greater potassium excretion than would be predicted from nitrogen loss.

In the present paper we further report highly significant correlations between urinary nitrogen and potassium both at 20 and 30° C. ($P < 0·001$) and also a significant correlation between creatine and potassium at 20° C. but not at 30° C. These correlations were for all degrees of severity of injury and at all intervals during the first 2 weeks following the injury. Thus, the effect of the higher ambient temperature is to reduce the overall excess urinary excretion of potassium as well as that of nitrogen.

Creatine is the most abundant extractive of muscle, and more than 95 per cent of the total body content of creatine is found in muscle as creatine phosphate. It is normally excreted in urine after conversion to creatinine, only small amounts of creatine itself being detected. In 14 normal subjects we found a daily urine output of 85 ± 11 mg. (mean ± s.d.).

Creatinuria is commonly observed in muscle diseases (Pennington, 1971). In diverse conditions involving acute wasting of muscle, such as when carbohydrate is absent from food, in diabetes, in hyperthyroidism, and during involution of the uterus following parturition, large increases in urine creatine are reported (Allison and Bird, 1964). After injury a marked rise in plasma creatine was observed in severely injured goats, treated or untreated with penicillin (Gillette, Oppenheimer, Mansberger, Johnson, and Kookootsedes, 1958). The rise in plasma creatine was much greater than that of the other nitrogenous constituents examined, suggesting a rapid release of creatine from muscle cells at a rate faster than the conversion process to creatinine can effect, or a failure of uptake by an effectively reduced muscle cell mass of the creatine synthesized in the liver, leading to incomplete renal tubular reabsorption and creatinuria. The results of our studies are shown in *Table IV*, where they are analysed period by period. The most striking feature is the up to fivefold increase above the normal excretion which was observed, and also that the creatine excretion was less in the first period for the 30° C. group (*t*-test, $P < 0·05$). This finding has subsequently been repeated in a further series after injury (Cuthbertson, Fell, Fleck, and Queen, 1972), and confirms the diminution in the response at the higher environmental temperature.

Table V.—RESULTS OF MULTIPLE REGRESSION $Y = aX_1 + bX_2 + c$, WHERE Y IS URINE NITROGEN (g. per day), X_1 IS FOOD NITROGEN (g. per day), AND X_2 IS FOOD ENERGY (MJ. per day)

AMBIENT TEMPERATURE (°C.)	PERIOD	*a*	*b*	*c*	*P*
20	1	−0·67	+0·87	+16·3	N.S.
	2	−0·30	+0·40	+4·4	N.S.
	3	−0·37	+0·95	+12·5	N.S.
	4	−0·40	+0·90	+11·5	N.S.
30	1	+0·45	−1·24	+7·8	<0·05
	2	+0·88	−0·59	+10·7	N.S.
	3	+0·48	−0·40	+13·8	N.S.
	4	+0·80	−0·81	+13·5	<0·1

Results are average values for each period, with all severities of injury taken together.

N.S., Not significant.

The urinary excretion of zinc is low. For 16 normal subjects we found a daily excretion of 496 ± 197 μg. (mean ± s.d.). It is not affected by urinary volume or dietary intake (Spencer, Osis, Kramer, and Samachson, 1971). More than 60 per cent of the total body zinc is in skeletal muscle and the urinary excretion is known to rise after injury (Henzel, De Weese, and Lichti, 1970). The results shown in *Table IV* demonstrate the two- to threefold increases found after injury, although there was no significant difference in the amount excreted by the two groups of patients.

The evidence of increased potassium, creatine, and zinc excretion in urine after injury clearly demonstrates the quantitative importance of muscle in the protein metabolic response to trauma.

5. Relation between Dietary Nitrogen and Energy and Urine Nitrogen Excretion after Trauma.—Normally one would expect urine nitrogen to be a variable dependent linearly on food nitrogen and food energy, the regression coefficient being positive for food nitrogen and negative for food energy. We tested this relationship in the injured subjects. The multiple linear regression of urine nitrogen on food nitrogen and food energy was computed for the mean intake and excretion values for each patient in each of the four time periods. The results from patients at 20° C. were analysed separately from those at 30° C. Statistically significant linearity was tested by analysis of variance. The results are shown in *Table V*. It is clear that there is never a significant linear relationship at 20° C. and indeed the regression coefficients do not even have the expected signs. At 30° C., however, the regression coefficients all have the expected sign and a statistically linear relationship is achieved in period 1 ($P < 0·05$) and nearly so in period 4 ($P < 0·1$).

6. Correlation between Urine Nitrogen and other Excretory Products of Tissue Catabolism.—Single correlation coefficients were computed for urine nitrogen on urine zinc, urine nitrogen on urine creatine, and urine nitrogen on urine potassium. Urine nitrogen always correlated significantly with urine zinc ($P < 0·005$), with urine creatine ($P < 0·001$), and with urine potassium ($P < 0·001$). Creatine correlated significantly with zinc ($P < 0·001$) and with potassium ($P < 0·01$) at 20° C. but not at 30° C. This further suggests that muscle catabolism is a major factor in the metabolic response and that this is somewhat reduced at ambient temperatures of about 30° C. The results are shown in *Table VI*.

Table VI.—CORRELATIONS BETWEEN URINE NITROGEN AND PRODUCTS OF MUSCLE-TISSUE CATABOLISM (CREATINE, ZINC, AND POTASSIUM) AND BETWEEN URINE CREATINE AND OTHER PRODUCTS OF MUSCLE-TISSUE CATABOLISM (ZINC AND POTASSIUM) FOR PATIENTS WITH ALL SEVERITIES OF TRAUMA AT ALL INTERVALS AFTER INJURY

AMBIENT TEMPERATURE (°C.)	CORRELATION	*r*	*P*
20	Nitrogen and zinc	0·5233	<0·005
	Nitrogen and creatine	0·5337	<0·001
	Nitrogen and potassium	0·6592	<0·001
30	Nitrogen and zinc	0·5167	<0·005
	Nitrogen and creatine	0·4565	<0·005
	Nitrogen and potassium	0·5964	<0·001
20	Creatine and zinc	0·5910	<0·001

30	Creatine and zinc	0·2970	N.S.
	Creatine and potassium	0·2219	N.S.

DISCUSSION

The results reported in the present paper allow two important conclusions to be drawn. First, the metabolic response to bony injury (mainly fractures) involves net catabolism of muscle tissue to a quantitatively important extent, and secondly, this response is significantly reduced in the severely injured patient if he is housed at 30° C. ambient temperature.

It has long been inferred that muscle breakdown is involved in the metabolic response to injury. Indeed, the early observations of Cuthbertson (1930) arose from an investigation of the calcium and phosphorus balance in patients with fracture of the long bones of the lower limbs, where there was found to be an unexpected considerable negative phosphorus balance but not a corresponding calcium deficit. Soft tissue seemed to be implicated and further investigations showed a marked loss of nitrogen and sulphur as well as of phosphorus in the first 10–12 days following fracture of a major long bone. These three elements were excreted in proportions which suggested that muscle might be the source of the loss. A few years later Cuthbertson and others (1939) observed similar responses in the rat given experimentally a fracture of femur, and they also reported a creatinuria which paralleled the increased urine-nitrogen loss. This work was not taken much further at the time owing to war-time conditions, but the importance of a dietary-dependent endogenous protein pool was demonstrated by Munro and Cuthbertson (1943) and Munro and Chalmers (1945), who found no increased urine nitrogen following fracture of the femur in the rat if the animals had been fed a protein-free, but calorie-sufficient, diet for some time before injury. They also showed that the proportion of protein in the pre-injury, but not post-injury, diet quantitatively affected the response to trauma. However, in spite of the well-accepted clinical observation of muscle wasting in severe injury and the above observations of Munro and his colleagues, some workers claim that the observed metabolic response to injury is simply that of the reduced voluntary food intake which usually follows major trauma (Abbott and Albertsen, 1963).

The results which we report quite clearly demonstrate the involvement of muscle catabolism in the presence of undiminished food intake, and that this response, entirely separate from dietary conditions, is diminished at the higher ambient temperature. The results of the regression analysis both confirm the effect of the 30° C. environment in reducing the metabolic response and also cast doubt on the value of intensive nutrition, in which high-calorie, high-nitrogen diets are given by intubation or intravenously in the early stages post trauma. Our results indicate that such measures in no way diminish the catabolic response of muscle tissue. It is true that, faced with a long-term apparently hypercatabolic state or with a patient who will be unable to feed normally for some time, intensive nutrition with high-energy regimens will be of value since nitrogen balance should be improved (Peaston, 1968).

The effect of environmental temperature on the metabolic response to trauma is a relatively recent finding. The first observation of a reduction in what Cuthbertson has defined as the 'flow' phase (Cuthbertson, 1942) was made by Caldwell in 1962. This report showed that an ambient temperature of 30° C. reduced negative nitrogen balance and mortality in rats with severe scalding injury. These observations have been confirmed by Barr and others (1968) and Davies and Liljedahl (1970) for man with severe burn injury.

The initial suggestion of Caldwell (1962) was that the warmer environment provided the heat required to evaporate the water that is continuously lost from burned skin and thus relieved the body of a heat burden which can easily exceed 3000 Cal. (12·5 MJ.) per day (Moyer and Butcher, 1967). This may be part of the value of the warmer environment to patients with burns, but it in no way accounts for the similar effect of temperature on the metabolic response to long bone injury in the rat (Campbell and Cuthbertson, 1967) or the results for man reported in the present paper. Unfortunately our experiments do not allow us to draw conclusions about the mechanisms involved. We do know that the corticosteroid response is not affected by the higher temperature, at least in the rat (Tilstone and Roach, 1969) and we feel that more evidence is needed before Caldwell's more recent suggestion (Caldwell, 1970) that the thyroid is definitely concerned can be accepted.

Johnston and others have been studying the effect of exposure to 30° C. on the metabolic response to trauma in patients undergoing elective abdominal surgery. They have recently reported their conclusions (Spivey and Johnston, 1972) and state that temperature does not affect the metabolic response in these patients but point out that the catabolic response to such trauma is usually minor. This agrees with our results from the less severely injured subgroup, but our overall results and those mentioned above from workers dealing with burn injuries quite clearly show that a reduced metabolic response can be achieved by increasing the ambient temperature to 30° C. A beneficial clinical response also seems clear in the burns cases, although we can put forward no conclusions at all about the progress of the long bone injuries other than that it is not impaired. Improved superficial wound healing in rats has already been reported by us (Cuthbertson and Tilstone, 1967). The parallel observations on some of our cases made by Fleck and Ballantyne (1971) in respect of the behaviour of the plasma proteins following injury indicate that at 28–30° C. there is much less disturbance with a diminished rise in acute phase reactants and a diminished fall in plasma-albumin concentration.

Davies (1970), following up the close correlation between the increased rate of nitrogen excretion and the increase in resting metabolic rate both in fractures and burns, has, with his Swedish collaborators (Barr and others, 1968), further demonstrated the beneficial effect of a warm environment (32° C.) on protein metabolism. They have shown that the catabolism of plasma albumin and IgG was increased as the severity of the burns increased and with burns the catabolic rate of these two proteins was reduced by nursing the patients at 32° C.

Campbell and Cuthbertson (1967) and Cuthbertson and others (1968) observed a 15–30 per cent fall in voluntary food intake in the rat at an environmental temperature of 30° C., but we have not found a significant fall in intake in our human patients. However, in an earlier report (Tilstone and Cuthbertson, 1970) we did consider the possible combined effects of the slight increase in intake of energy together with possibly reduced heat loss at 30° C. on urine nitrogen at 30° C., and concluded this to be still insignificant. Similarly skin losses of nitrogen, which amount to about 0·55 g. per day for a sedentary man in a comfortable environment (Calloway, Odell, and Margen, 1971), would not be expected to differ at 30° C. to an extent which would compensate for the reduced excess nitrogen excretion.

Patients vary in the intensity and duration of their response to injury, particularly in terms of heat production (Kinney, Long, and Duke, 1970). Involved in this is the effective circulating blood-volume, the integrity of the particular reaction of the neuro-endocrine system, the nutritional state in respect of its energy reserves, and the effect of environmental temperature.

Following moderate to severe injury there is first the 'ebb phase' of diminished heat production corresponding with the 'shock' period. This depression, as Threfall (1970) has pointed out, is not due to lack of oxygen supply but possibly is effected through changes in the thermoregulatory mechanism. The changes characteristic of tissue hypoxia in experimental animals do not tend to occur until the point when death seems certain. When the metabolic tide 'turns' the increased heat production of the 'flow phase' is apparently brought about through changes in the sites of thermogenesis. The application of heat during this stage in experimental animals has an adverse effect on survival, possibly due to their low thermal capacity. Man has a much greater thermal capacity and heat may be advantageous at an earlier stage than we have applied it, once appropriate blood transfusions have been effected. Cases involving brain damage, however, are an exception.

During the 'flow phase' when heat production and oxygen consumption are increased the hyperglycaemia and glycosuria usually disappear. When the environmental temperature is brought up to thermoneutrality for man, i.e., 28–30° C., the need for increased oxidation of protein and for carbohydrate intermediates and the products of their oxidation is also reduced (Kinney and others, 1970). The increased body temperature associated with moderate to severe injury—traumatic fever—does not appear to be affected by the thermal environment.

The increases in urinary potassium, zinc, and creatine as well as nitrogen at normal ward temperature lend further emphasis to the view that following trauma the major change in metabolism in the 'flow phase' is increased catabolism rather than diminished anabolism.

Acknowledgements.—D. P. Cuthbertson wishes to express his sincere thanks to the Medical Research Council for a grant in aid of this research. The authors are grateful for the facilities provided in the Department of Pathological Biochemistry, Glasgow Royal Infirmary, by Professor H. G. Morgan and the Board of Management of the hospital. They also wish to acknowledge their indebtedness to Professor W. A. Mackey and his nursing staff and to Mr. John White, Chairman of the Department of Orthopaedic Surgery and Accident Unit, and his surgical colleagues and nursing staff for their great co-operation and for making available space for the erection of the special air-conditioned cubicles. Skilled technical assistance has been provided by Miss Christine Hall and Mrs. Erin Canning.

'CURATIVE' SURGERY IN CARCINOMA OF THE COLON INVOLVING DUODENUM

A REPORT OF 6 CASES

By HAROLD ELLIS, M. NAUNTON MORGAN, AND CHRISTOPHER WASTELL
SURGICAL UNIT, WESTMINSTER HOSPITAL, LONDON

SUMMARY

Six examples of duodenal involvement by colonic cancer are reported. Two had an associated duodenal fistula. Radical surgery was carried out in all 6 cases, 3 of whom remain alive and free from recurrence up to 6 years later.

INVASION of adjacent structures by a neoplasm is frequently synonymous with inoperability. The common situation where this general rule meets with its greatest exception is in cancer of the large bowel; here every experienced abdominal surgeon will have encountered examples where radical excision of the growth, together with adjacent adherent or invaded viscera, has been followed by relief of often intolerable symptoms and in a number of cases by long-term survival.

In this paper 6 examples of duodenal involvement by right-sided colonic carcinoma in which radical monobloc resection was possible are reported; in 2 cases there was an established duodenocolic fistula. Two tumours were also adherent to the right kidney, and another had invaded both the anterior abdominal wall and a loop of small intestine.

Brief reports of these 6 cases are as follows. The main features are summarized in *Table I*.

Table I.—DETAILS OF THE CASES IN THE PRESENT SERIES

CASE	AGE AND SEX		SITE	OTHER VISCERA INVOLVED AND RESECTED	RESULT
1. I. H.	45	M.	Transverse colon	1. Third part of duodenum 2. Anterior abdominal wall 3. Loop of jejunum	Alive and well 6 yr. later
2. H. A.	66	M.	Hepatic flexure	1. Second part of duodenum (fistula) 2. Perinephric fat 3. Posterior abdominal wall	Died 1 yr. 4 mth. postoperatively (carcinomatosis)
3. I. H.	70	M.	Ascending colon	1. Second part of duodenum	Alive and well 3 yr. 7 mth. later
4. C. M.	74	F.	Ascending colon	1. Second part of duodenum (fistula) 2. Posterior abdominal wall 3. Perinephric fat (necessitating right nephrectomy)	Died 10 mth. postoperatively (carcinomatosis)
5. J. McK.	45	M.	Ascending colon	1. Second part of duodenum	Alive and well 2 yr. later
6. J. D.	44	M.	Ascending colon	1. Second part of duodenum 2. Right kidney	Died 1 yr. 4 mth. postoperatively (carcinomatosis)

CASE REPORTS

Case 1.—Mr. I. H., aged 45 years, was admitted to another hospital in October, 1966, with a mass in the right iliac fossa. Laparotomy revealed a carcinoma of the transverse colon with a pericolic abscess. A caecostomy was performed. In November, 1966, a further laparotomy was carried out with drainage of an abdominal wall abscess. Biopsy showed an adenocarcinoma and the lesion was considered inoperable.

The patient was transferred to the Westminster Hospital for consideration of radiotherapy or cytotoxic therapy. On admission he was thin and anaemic (haemoglobin 12·7 g.). Faeces were discharging through the caecostomy and there was a palpable mass in the right iliac fossa. This mass was adherent to the laparotomy scar, opening on to which were several purulent sinuses. It was decided first to defunction the tumour region and then, if possible, to carry out a resection.

The first operation was performed on 23 Dec., 1966 (H. E.). A long, oblique, left iliac fossa incision revealed a tumour of the transverse colon which was adherent to the abdominal wall, to a loop of small intestine about 1·5 m. from the duodenojejunal junction, and to the third part of the duodenum. The terminal ileum was divided, the splenic flexure was mobilized and divided, and their distal and proximal ends respectively were closed. An ileosplenic flexure end-to-end anastomosis was then performed (*Fig.* 1). The large bowel was thus defunctioned, as a result of which the infection rapidly subsided and the patient's general condition improved.

The second operation was performed on 10 Jan., 1967 (H. E.). As a preliminary the caecostomy was mobilized and closed. Wide excision of the anterior abdominal wall was performed to include the original scar and the discharging sinuses leading down to the tumour mass. The whole of the defunctioned large bowel was resected *en bloc*, together with the anterior abdominal wall, a portion of the third part of the duodenum which was adherent to the tumour, the loop of involved jejunum, and the spleen. The duodenal defect was closed with two layers of catgut transversely and continuity of the small intestine was restored by end-to-end-anastomosis (*Fig.* 2).

Pathological examination revealed a moderately differentiated adenocarcinoma of the transverse colon infiltrating the pericolic fat and the anterior abdominal wall. It was involving the adherent duodenum and small intestine superficially but had not infiltrated into their muscle walls.

The patient made a satisfactory recovery and remains alive and well 6 years later (*Fig.* 3).

Case 2.—Mr. H. A., aged 66 years, was admitted in March, 1969, with a 12-month history of diarrhoea and colicky abdominal pain. There was a palpable mass in the right hypochondrium and a barium-enema examination revealed a carcinoma of the hepatic flexure with a fistula between the colon and duodenum (*Fig.* 4).

Operation was carried out on 11 March (H. E.). There was an extensive carcinoma of the hepatic flexure with a fistula into the second part of the duodenum. The adjacent posterior abdominal wall and perinephric fat were invaded. A right hemicolectomy was performed with excision of the involved duodenum, the resultant large defect being closed with two layers of catgut.

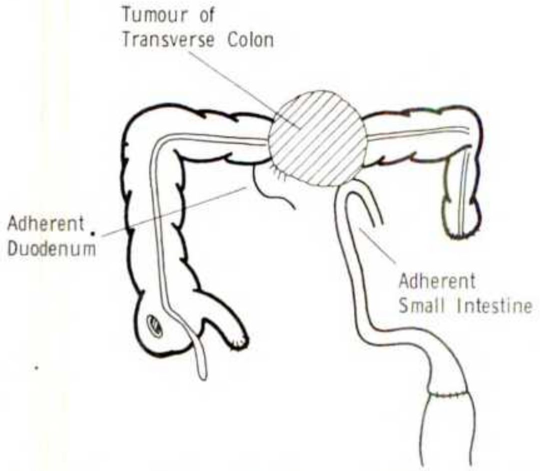

FIG. 1.—*Case* 1. Findings at laparotomy and the short circuit of the tumour of the transverse colon.

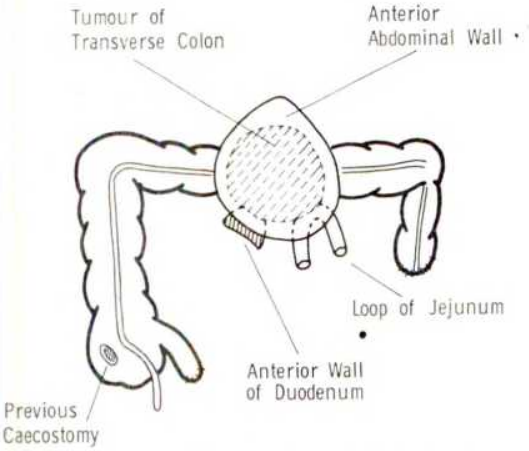

FIG. 2.—*Case* 1. Diagram of the resected specimen.

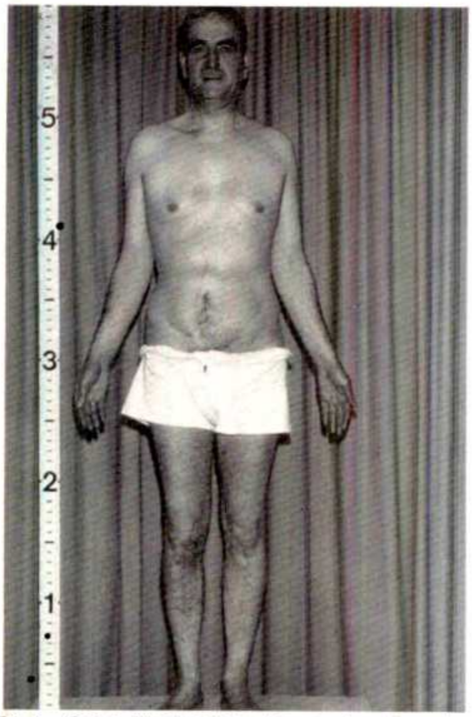

FIG. 3.—*Case* 1. Patient 5 years after resection of a carcinoma of the transverse colon invading the anterior abdominal wall, jejunum, and duodenum.

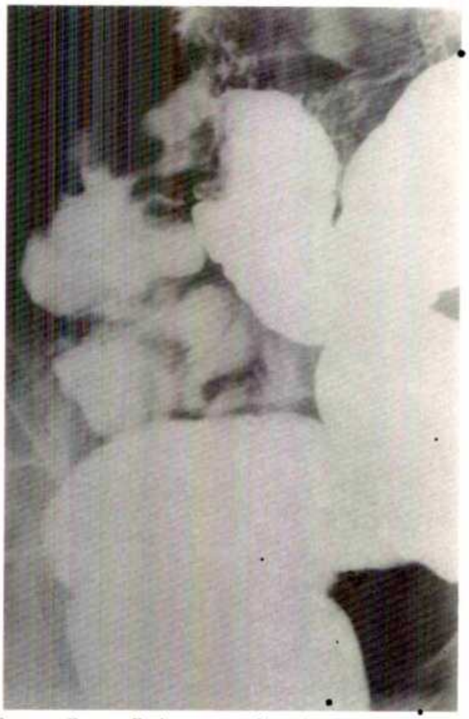

FIG. 4.—*Case* 2. Barium-enema film, showing a carcinomatous stricture of the ascending colon fistulating into the duodenum. Note the reflux of barium into the duodenum and upper jejunum.

Pathological examination of the specimen revealed a well-differentiated adenocarcinoma with fistulation into the adjacent duodenum. The lymph-nodes were not invaded.

The patient made an uneventful recovery but was admitted to Maidenhead Hospital in July, 1970, with carcinomatosis where he died 1 year and 4 months after the operation.

Case 3.—Sir I. H., aged 70 years, was admitted in March, 1969, complaining of diarrhoea, right-sided abdominal pain, loss of appetite, and anaemia over a 9-month period. Examination revealed a mass over the right upper quadrant of the abdomen. The haemoglobin was 7·1 g.

After a blood transfusion laparotomy was carried out on 18 April (C. W.). There was a large mobile carcinoma of the ascending colon which was invading the second part of the duodenum. Right hemicolectomy was performed with resection of a 3-cm. diameter circle of duodenum. The duodenal defect was closed transversely with inner catgut and outer interrupted thread.

Pathological examination revealed an adenocarcinoma invading the serosal surface of the duodenum. The lymph-nodes were not involved.

Recovery was uneventful and the patient is alive and well, at the time of this report, 3 years and 7 months later.

Case 4.—Mrs. C. M., aged 74 years, was admitted in November, 1969, with a 4-year history of anaemia and loss of weight. Examination revealed a mass in the right upper abdomen. The haemoglobin was 7·1 g.

Laparotomy was carried out on 2 Dec. (H. E.) after a preliminary blood transfusion. There was a carcinoma of the ascending colon which had infiltrated the posterior abdominal wall and the perinephric fat of the right kidney and also had fistulated into the second part of the duodenum. A monobloc excision taking the ascending colon, right kidney, and a segment 7·5 cm. long and 4 cm. wide on the anterior duodenal wall was performed. The duodenum was closed transversely with one layer of catgut. Recovery was uneventful.

Pathological examination revealed an annular carcinoma fistulating into the duodenum and invading extensively into the perinephric fat, although the kidney itself was not invaded. Adjacent lymph-nodes were not involved.

The patient developed recurrence of the tumour and died in Westminster Hospital on 12 Sept., 1970.

Case 5.—Mr. J. McK., aged 45 years, was admitted in September, 1970, with a 1-year history of upper abdominal pain and diarrhoea. The haemoglobin was 10·4 g. A barium-enema examination revealed a filling defect just proximal to the hepatic flexure.

An operation on 13 Oct. (M. N. M.) a large tumour of the ascending colon was resected together with the adjacent second part of the duodenum, which was closed transversely in two layers.

Pathological examination showed an annular carcinoma of the colon which was poorly differentiated. The wall of the duodenum was invaded, but the mucosa had not been breached. The lymph-nodes were not involved.

The patient is alive and well over 2 years following operation.

Case 6.—Mr. J. D., aged 44 years, was admitted in April, 1971, with a 6-month history of right-sided abdominal pain and weight-loss. There was a tender mass in the right side of the abdomen and a barium-enema examination showed a filling defect in the ascending colon. Operation on 15 April (M. N. M.) revealed a carcinoma of the ascending colon which had invaded the second part of the duodenum and the right kidney. Right hemicolectomy, right nephrectomy, and excision of the segment of the anterior wall of the duodenum, measuring 2·5 cm. by 7·5 cm., was performed in one procedure. The duodenum was closed transversely in two layers and as there was some narrowing of the lumen an anterior gastro-enterostomy was performed. There was postoperative delay in function of the gastro-enterostomy which was re-explored on 11 May. The stoma appeared widely open and no further procedure was necessary. Following this second laparotomy the patient made a satisfactory recovery. A subsequent barium-meal examination showed free flow of barium through the duodenum.

Pathological examination revealed a poorly differentiated adenocarcinoma of the ascending colon invading both the right kidney and the duodenum although it had not penetrated the muscularis of the duodenum. The lymph-nodes were free from tumour.

The patient died from recurrent disease 16 months after operation.

DISCUSSION

The surgeon setting out to explore a patient with a carcinoma of the colon hopes to find a localized tumour which is amenable to a standard resection procedure. When he encounters disseminated disease or adherence to adjacent structures, considerable judgement is required in order to decide on the correct treatment.

Deposits in the liver, provided that gross hepatic destruction has not taken place, should not deter him from resecting the primary growth and thus relieving or preventing intestinal obstruction, fistulation, etc. Our figures from Westminster Hospital show that one-third of patients submitted to such palliative resection will live for more than 1 year (Oxley and Ellis, 1969).

Adjacent structures which may be found adherent to the growth include the anterior or posterior abdominal wall, small intestine, the greater curvature of the stomach, spleen, duodenum, pancreas, kidney, ureter, bladder, uterus, and Fallopian tubes. This adherence may be entirely inflammatory (Cooke, 1956), but it is wise to assume that tumour invasion has occurred in planning resection. A trial resection is often necessary to assess whether or not *en bloc* removal is a reasonable proposition, and here the patient's general condition and the presence or absence of dissemination of tumour elsewhere should be taken into consideration. Distant peritoneal nodules, the presence of gross ascites, and heavy liver involvement contra-indicate radical surgery.

The results of radical surgery for advanced local disease are, under the circumstances, surprisingly good. Van Prohaska, Govostis, and Lasick (1953) reviewed 225 patients undergoing resection for carcinoma of the colon and rectum; 21 of these (9 per cent) required resection of adjacent structures, which included spleen, abdominal wall, bladder, etc. There was only 1 operative death and 14 of these patients (67 per cent) were alive 2–13 years later. Of particular interest in the present context were 2 patients who underwent right hemicolectomy together with pancreaticoduodenectomy; these survived operation but died 2½ years and 11 months after surgery respectively from metastatic disease. Jensen, Balslev, and Nielsen (1970) reported experience of 554 patients with carcinoma of the colon; 406 underwent resection and 60 of these cases required resection of the abdominal wall or other organs. Of these 60 patients, 23 were found to have only inflammatory adhesions and 13 of these were alive after 5 years. The remaining 37 cases had malignant invasion of adjacent structures and 5 of these were alive 5 years later. Again of particular relevence were 3 patients who had a resection of adjacent duodenum; 2 of these proved to have malignant adherence but both died in the postoperative period. El-Domeiri and Whiteley (1970) noted 10 examples of invasion of the anterior abdominal wall in a series of 327 patients with carcinoma of the caecum undergoing resection; there was 1 postoperative death and 7 of the 9 survivors were still alive at the time of the review, 5 already having survived for 5 years.

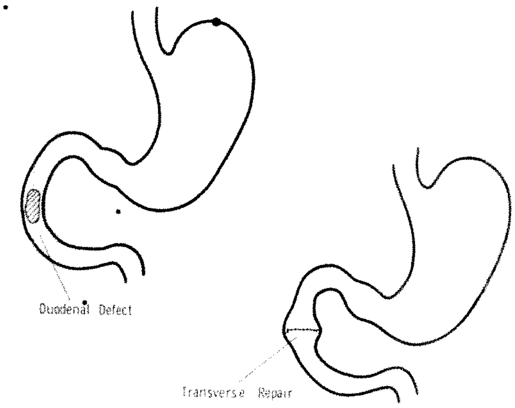

FIG. 5.—Technique of repair of a duodenal defect adopted in this series of patients.

Very few reports deal specifically with the problem presented by adherence or fistulation of cancers in the region of the hepatic flexure and the duodenum. Juvara and Radulescu (1969) encountered 4 such cases in the course of 124 right hemicolectomies. Two of these had a coloduodenal fistula and 2 had malignant involvement of the duodenal wall without fistula formation. In our own experience in the Surgical Unit at the Westminster Hospital 6 cases of duodenal involvement, 2 with a fistula, have been encountered in the course of the past 5 years.

CLOSURE OF THE DUODENAL DEFECT

Having carried out adequate excision of the affected duodenum with a healthy cuff of adjacent bowel, there is the problem of adequate closure of the resultant duodenal defect. In our own cases this has been achieved without difficulty by simple one- or two-layer transverse closure (*Fig.* 5) and we have not encountered problems of either leakage or stenosis, although in 1 instance it was considered prudent to perform a gastrojejunostomy. Fortunately in none of these cases was the pancreatic duct involved since, under such circumstances, it would be necessary to consider a formal pancreaticoduodenectomy.

Juvara and Radulescu (1969) found in their cases that simple repair of the duodenal defect was not possible; they described an ingenious technique in which, following the right hemicolectomy, a loop of the intact terminal ileum just proximal to the ileocolic anastomosis was sutured as a patch over the duodenal defect, stitching the serous surface of the ileum around the edges of the duodenal defect by a series of interrupted seromuscular sutures (*Fig.* 6). This technique of closure of wounds of the duodenum by sewing the intact serosa of a jejunal loop over the defect was described in an experimental animal by Kobold and Thal (1963), and was used for closure of experimentally produced grossly infected perforated duodenal stumps by Jones, Gregory, Smith, Saito, and Joergenson (1964). The technique has been used clinically to patch difficult intestinal perforations (McKittrick, 1965; Ballinger, McLaughlin, and Baranski, 1966; Jones and Steedman, 1969). In our own laboratory we have confirmed the efficacy of this method in the closure of large duodenal defects in the dog. Subsequent histological studies showed that the duodenal mucous membrane grew from the cut edge of the defect over the serosal surface of the jejunal patch so that eventually the lumen of the duodenum became relined with mucous membrane. In 1 animal a fistula between the duodenum and the jejunum used for the patch developed. In view of this it is advisable to use as proximal a piece of bowel as possible. There is no doubt that in any case which we might encounter where duodenal closure is impossible by direct suture, whether such a defect resulted from surgical excision, trauma, or chronic perforation, we would not hesitate to employ this technique.

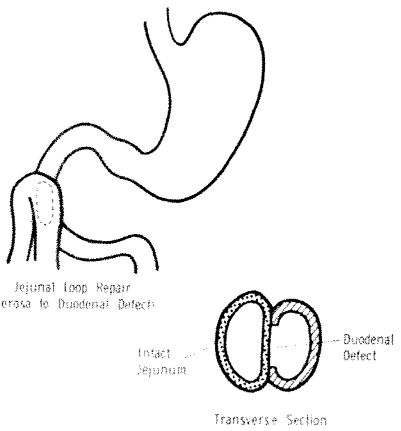

FIG. 6.—Use of intact jejunal loop advocated for the repair of difficult duodenal defects and used in our experimental studies.

OESOPHAGEAL PERFORATION DURING ABDOMINAL TRUNCAL VAGOTOMY FOR DUODENAL ULCER

By J. J. PRICE, S. J. A. POWIS, AND D. M. MORRISSEY*

QUEEN ELIZABETH HOSPITAL, QUEEN ELIZABETH MEDICAL CENTRE, EDGBASTON, BIRMINGHAM

SUMMARY

A retrospective survey of patients having truncal vagotomy for duodenal ulceration has been carried out. In this series 41 cases of oesophageal perforation occurred; 29 were recognized at the time of operation, 6 were diagnosed postoperatively, and in the remaining 6 the time of diagnosis was not specified. Two of the 29 patients in whom the oesophageal perforation was recognized at the time of operation died, as did 2 of the 6 cases diagnosed postoperatively. An increase of mortality and morbidity occurred in those diagnosed postoperatively. The importance of confirming oesophageal integrity at the conclusion of vagotomy is stressed.

DURING the past decade vagotomy and gastric drainage has gained acceptance as a treatment of chronic duodenal ulceration (Goligher, Pulvertaft, de Dombal, and others, 1968a, b; Small and Jahadi, 1970). The mortality of this prodecure is reported to vary between 0 and 3·3 per cent (Holt and Lythgoe, 1961; Mead, 1967). Oesophageal rupture is rarely mentioned as being responsible for mortality or morbidity following vagotomy, only approximately 30 cases appearing in the literature (McBurney, 1969; Postlethwait and Dillon, 1969; Wichern, 1970).

In the present series 35 cases are discussed in detail; the remaining 6 are known to have occurred but full clinical data are not available. The importance of operative diagnosis has already been alluded to (Postlethwait and Dillon, 1969) although the necessity for early diagnosis has not been stressed.

MATERIALS AND METHODS

One hundred and twenty-five surgeons in the Midland Region were requested to provide information regarding their experience of oesophageal injury during vagotomy for duodenal ulceration in the 5-year period 1965–9.

Initial inquiry involved a request for knowledge of the injury; subsequently all those who met with this complication were asked to complete a simple questionnaire (*Table I*).

Computer data are available for all admissions to selected hospitals in the Birmingham Region Hospital Board area. From this information the incidence of perforation and the contribution of this injury to the mortality of vagotomy can be deduced.

RESULTS

Of the 35 patients with full clinical details, all had a perforation of the oesophagus during the course of an elective abdominal truncal vagotomy for duodenal ulcer. Thirty-three of the 35 patients were male and 2 were female, with an average age of 54·7 years (range 36–74 years). The sex and age distribution is in accordance with that for surgical treatment of duodenal ulcer in this region. Twenty-two operations in which perforation of the oesophagus occurred were performed by a surgeon of registrar status and 13 by a surgeon of consultant status. In 7 cases after recognition of a breach of the oesophagus the assistance of a consultant was sought by the junior surgeon performing the operation.

Table I.—THE QUESTIONNAIRE USED IN THE PRESENT SERIES

Name ....

Age................ Sex................ Hospital No.........

Status of surgeon (registrar/consultant).........................

Date of operation.................................

	Incision used for vagotomy:—
	Presence of hiatus hernia on preoperative barium meal—YES/NO
	Presence of hiatus hernia at laparotomy—YES/NO
	Operation findings:—
	Method of dissection of vagus nerve:—
Ryle's tube	in oesophagus at time of vagotomy:—
Diagnosis of perforation of oesophagus	at operation:—
	postoperatively:—
	OUTCOME:—

Thirty-one of the 41 oesophageal perforations in this series occurred in 4026 patients for whom computer data are available, giving an incidence for this injury of 0·8 per cent. The other 10 perforations occurred in hospitals without computer facilities.

Of the 35 cases of oesophageal perforation, 14 occurred when the vagotomy was performed through a midline incision and 16 through a paramedian one. In 5 cases the incision used was other than these or unspecified.

The presence of a hiatus hernia was diagnosed radiologically preoperatively in 16 patients and was confirmed at operation in all of these. Several methods of dissection of the vagus nerves were used including blunt dissection by finger or gauze and in some instances by cholecystectomy forceps or scissors. No method was especially liable to result in oesophageal damage. Several surgeons used a nerve hook to identify the vagus nerves or branches thereof, but in on case was it considered that an oesophageal perforation was attributable to this instrument. A nasogastric tube was invariably in place in the oesophagus (26 cases). In 29 cases the oesophageal damage was diagnosed at the time of operation and in 6 postoperatively. Modes of postoperative presentation included pneumoperitoneum with collapse of the lower lobes with or without empyema, pleural effusion, or pneumothorax. The mortality-rate of those with perforation diagnosed at the time of operation was 2 out of 29 cases, death being due to intraperitoneal sepsis in both. Death in both the patients whose diagnosis was delayed was also due to intraperitoneal sepsis.

---

* Requests for reprints to: Mr. D. M. Morrissey, Queen Elizabeth Hospital, Queen Elizabeth Medical Centre, Edgbaston, Birmingham B15 2TH.

All the patients in whom the leak was diagnosed postoperatively had either a laparotomy or thoracotomy for suture of the perforated oesophagus or drainage of the associated sepsis. All the patients in this group had a protracted postoperative course, in 2 extending to 9 weeks' stay in hospital, and in both of whom a third operation was necessary.

DISCUSSION

The age and sex distribution in this series is similar to that in other published work (Mead, 1967; Small and Jahadi, 1970) and therefore the damage was neither age- nor sex-related. It was not the experience of the surgeons whose cases are recorded here that dissection of the vagus nerves was arduous on account of the patient's body configuration or weight, but in 7 cases vagal dissection was complicated by peri-oesophagitis and in 16 instances was associated with a hiatus hernia. This incidence of hiatus hernia (46 per cent) is even greater than may be expected in a series of patients with or without upper gastro-intestinal tract symptoms (Pridie, 1966; Dyer and Pridie, 1968).

The frequency of oesophageal rupture as a complication of truncal vagotomy in this series is 0·8 per cent. This is much higher than would be expected from other published work, but must represent a more realistic incidence in view of the number of patients and hospitals concerned.

Diagnosis is made at the time of operation, when either the nasogastric tube is seen within the oesophageal lumen or the emergence of gastric contents from the site of perforation is noted. In 2 cases there were two perforations of the oesophagus where the oesophagus hung transfixed with a tape across its lumen. It is, therefore, important to examine carefully the remaining oesophagus within the operative field if one leak is detected. Early diagnosis has a profound effect on the prognosis of the patient, for if the leak is closed, either with absorbable or non-absorbable sutures in one or two layers, postoperative morbidity or mortality attributable to the damage is rarely seen. If the diagnosis is delayed the postoperative period may be complicated by chronic intraperitoneal and intrapleural sepsis. If these conditions are present in the post-vagotomy period the possibility of oesophageal perforation must be considered and investigated. Confirmation of the diagnosis radiologically makes early surgery mandatory to drain any collection there may be and to repair the perforation, for the greater the delay the worse the prognosis is. The mortality-rate in those patients in the present series with an operative diagnosis is 7·2 per cent (2 deaths in 29 patients), which compares favourably with the mortality of those patients in whom diagnosis of the perforation is delayed (2 deaths in 6 patients).

As oesophageal damage is likely to continue to occur in a few cases a method of early diagnosis must be considered, as the sequelae of delay may be very severe.

Diagnosis must be made at the time of laparotomy and, to this end, either the nasogastric tube should be withdrawn into the oesophagus and a dye injected or a double-lumen nasogastric tube should be used with one orifice opening into the oesophagus down which the dye may be injected. If these methods seem unreasonable then at least at the completion of the vagotomy the oesophagus should be very carefully inspected, not forgetting that perforation may occur in the posterior and posterolateral wall of the oesophagus, as it did in one-third of the cases in this series.

An appeal is made by the authors for reports from readers of their experience of this injury to the oesophagus during abdominal truncal vagotomy for duodenal ulcer. Could any such reports please be sent to Mr. D. M. Morrissey.

Acknowledgements.—We wish to thank all members and guests of the West Midlands Surgical Society who replied to the questionnaire and allowed us access to the notes of their patients.

We also wish to thank Miss Wall of the Regional Statistics Department, Birmingham Regional Hospital Board, for providing the computer information.

CIRCUMFERENTIAL OESOPHAGEAL MYOTOMY

By JAMES S. DAVIDSON

BRADFORD ROYAL INFIRMARY

SUMMARY

Circumferential division of the oesophageal muscle combined with hiatal hernia repair has been carried out in 26 patients, 19 of whom had a peptic stricture. The object of the procedure is to achieve slight elongation and relaxation of the oesophagus so as to make reduction of the hernia easier in the presence of slight degrees of oesophageal shortening and to reduce the likelihood of recurrence. The rationale and technique are described and details of illustrative cases are given. The postoperative radiological appearances, which are somewhat unusual, are illustrated. The indications and contra-indications are discussed. It is claimed that while circumferential myotomy is useless in the presence of gross shortening of the oesophagus it is of value in borderline cases where reduction of the hernia can be effected only by exerting slight tension on the oesophagus.

IN the presence of a peptic stricture with acquired shortening of the oesophagus, reduction of the hernia may be difficult or impossible and recurrence is likely. In 1963 d'Abreu, discussing this problem, said: 'Unfortunately, and I think this is becoming more apparent, adequate hernia operation is often impossible once stricture formation has developed. At thoracotomy in some patients, the oesophagus can be returned to its normal site and with its true length; if, however, the shortening of the oesophagus is material, an ominous sight for the surgeon is the cone-like appearance of the diaphragm round the elevated cardio-oesophageal junction. I now believe that, if the oesophagus has to be dragged down below the diaphragm under tension, the results will be disappointing.' If by some means even a small amount of lengthening and relaxation of the oesophagus could be produced this would increase the number of cases of peptic stricture suitable for treatment by hernial repair, which, in properly selected patients, has advantages over other forms of treatment such as dilatation or resection.

The author's interest in this problem was stimulated by experience with local resection of small carcinomas of the oesophagus and direct oesophageal anastomosis (Davidson, 1967a). In order to do this operation successfully it is necessary to cut close to the growth. It was found best to begin by dividing the muscle coats transversely above and below the tumour. The muscle then retracts upwards and downwards leaving bare mucosa and making it easier to see the mucosal extent of the carcinoma. It was found also that in some instances when the oesophagus is completely divided, contraction of the longitudinal muscle distracts the cut ends to such an extent that it is difficult to reapproximate them. From such observations it was felt that circumferential division of the longitudinal muscle might be of help in cases of peptic stricture where there was a degree of shortening of the oesophagus sufficient to make reduction of the hernia a little difficult. Initially, therefore, the object of such a myotomy was to gain additional length of oesophagus and to relieve the tension in it. As time has passed it has been realized that the procedure may have other advantages and it has been used in some patients with hiatal hernia uncomplicated by stricture.

ANATOMY AND PHYSIOLOGY

There are a number of relevant anatomical and physiological points.

The oesophageal muscle is a well-developed structure. It is relatively a good deal thicker than that of the stomach or small or large intestine. The longitudinal muscle is particularly well developed and unlike the condition usually found in the digestive tube it is as stout as, or in places stouter than, the the circular layer.

The mucous membrane is only loosely attached to the muscle coat by the submucosa. Considerable sliding movement is possible between them. This loose attachment allows the muscle coat to retract when divided transversely and is an important factor in the release of axial tension and the slight elongation of the oesophagus produced by transverse myotomy.

The mucosa is relatively inextensile, having no transverse folds. It is the main obstacle to extending the length of the oesophagus. However, it is not altogether inelastic and when there is a sliding hernia with elevation of the squamocolumnar mucosal junction there may be some redundancy of the mucosa. Stiennon (1968), discussing tertiary contractions in the oesophagus, maintains that transverse mucosal folds may be present when factors maintaining oesophageal length in spite of longitudinal muscle contractions are negated. He refers to hiatal hernia where the inferior attachments of the oesophagus are stretched.

Circumferential myotomy has not been found to cause dysphagia. The passage of peristaltic waves along the oesophagus depends on the continuity of the preganglionic vagal nerve-supply but not on the integrity of the muscle coat. If the oesophageal wall is divided and the superficial nerve plexus left intact the peristaltic wave can still pass normally over the oesophagus (Wright, 1965).

During deglutition and eructation there is an upward movement of the oesophagogastric junction. This is due both to traction by laryngeal elevation and to shortening of the oesophagus as a result of contraction of its longitudinal muscle (Inglefinger, 1958; Code, Kelley, Schlegel, and Olsen, 1962). Johnson (1966) placed markers on the mucosa and muscle of the oesophagus and on the margin of the hiatus in dogs. He showed that immediately after deglutition the markers on the mucosa and the muscle began to rise. This movement was still more marked on eructation. He mentions contraction of the longitudinal muscle and of the muscularis mucosae as causing this upward movement. Dey, Gilbert, Roskelley, and Trump (1945, 1946) claimed that in the dog electrical stimulation of the vagi produced shortening of the oesophagus sufficient, in some instances, to produce a hiatal hernia. The cardia resumes its normal position after swallowing by the elastic recoil of its inferior fascial attachments (Allison, 1970). When there is a sliding hernia this elastic recoil no longer takes place. As the upper part of the oesophagus retains its normal fixation in the crico-pharyngeal region, to the posterior wall of the trachea, and to the left main bronchus while the fixation of its lower end is deficient, the longitudinal muscle acts on the region of the cardia in a relatively unopposed manner tending to elevate it further. Whether contraction of the longitudinal muscle can ever be a primary cause of hiatal hernia or whether weakening of the inferior attachments of the oesophagus must occur first is not known, but it is of interest that there is a relatively high incidence of hiatal hernia in association with diffuse muscle spasm of the oesophagus (Creamer, 1962).

RATIONALE OF CIRCUMFERENTIAL OESOPHAGEAL MYOTOMY

This procedure was first used in the treatment of peptic stricture and it is in this connexion that its rationale is mainly considered. As will be discussed later, it may also have a place in the treatment of some cases of hiatal hernia uncomplicated by stricture.

In the presence of a stricture with shortening of the oesophagus there are at least three forces tending to result in inadequate reduction and recurrence of the hernia. Circumferential myotomy is an attempt to counteract them.

1. When reduction of the hernia is achieved by pulling the oesophagogastric junction down under tension there is an immediate upward pull tending to make repair ineffective and to cause recurrence. Transverse myotomy, by giving a little added length to the oesophagus, reduces this immediate upward traction. It is difficult to measure accurately the amount of lengthening of the oesophagus produced. It certainly varies from case to case. One way of taking this measurement is to determine the distance from the inferior margin of the aortic arch to the oesophagogastric junction with the latter held down under slight tension before and after myotomy. We make the measurement using a length of silk thread. The amount of elongation which can be obtained is small, being in the region of 2–3 cm. However, even this small amount may mean the difference between success and failure in achieving satisfactory repair and competence of the cardia. On occasion where myotomy has not been done and repair of the hernia resulted in a palpably taut oesophagus, myotomy done at this stage has produced obvious relaxation of the oesophagus.

2. As has already been described, the longitudinal muscle exerts an upward pull on the cardia. It is reasonable to assume that when it is divided transversely its action on the cardia will be reduced and that it will dissipate its efforts in causing distraction at the site of myotomy (*Fig.* 1).

3. If there are chronic inflammatory changes in the oesophageal muscle, fibrous contraction may continue postoperatively, causing recurrence of the hernia in much the same way as it produces herniation by traction following corrosive stricture of the oesophagus (Imre and Wooler, 1969). If the muscle layers are divided transversely any further shortening they may undergo should, in theory, result in further separation of their cut ends rather than a direct elevation of the oesophagogastric junction.

If the myotomy is to achieve the objectives for which it was designed, the oesophagogastric junction must be firmly fixed at the time of hernial repair. In the presence of shortening of the oesophagus it is doubtful if any method relying on the diaphragm for fixation is adequate. Possibly the best method of repair in such circumstances is that described by Hill (1967), where the upper part of the lesser curvature is firmly anchored to the median arcuate ligament.

This myotomy has been used to relax and extend the oesophagus in a few patients with sliding hiatal hernia uncomplicated by stricture. Sometimes, when there is a hernia of long standing and with a large amount of slide, it has been found difficult to restore the oesophagogastric junction to its normal position even though there were no obvious chronic inflammatory changes in the deeper layers of the oesophageal wall. In such patients the findings suggest that the oesophageal muscle has become adapted over a long period to its shortened state and will not immediately resume its normal length. It is tentatively suggested that this type of shortening is a true entity differing from the classic acquired shortening due to chronic inflammatory changes in the oesophageal wall.

TECHNIQUE

During the induction of anaesthesia the anaesthetist passes a large stomach tube into the oesophagus. This is more easily and more safety done at this stage than later on during the operation. A left thoracotomy or thoraco-abdominal incision is made. The oesophagus is mobilized up to the aortic arch. The stomach tube is advanced down the oesophagus until held up by the stricture. This is a good way of determining the exact level of the stricture. Account is then taken of the pathological changes in the oesophageal wall and a decision is made as to whether or not it is reasonable to attempt reduction of the hernia. In many instances it will be obvious that reduction is impossible. Where reduction seems feasible attention is turned to the vagi. If they are embedded in an inflamed, swollen, oesophageal wall and are acting as taut cords they are divided. Otherwise, they are isolated and held away from the oesophagus on threads. Myotomy is then done 2–3 cm. above the stricture using blunt-pointed scissors. This site is chosen as there is no risk of encountering the base of an unsuspected ulcer at this level and also because more movement is possible between the mucosa and the muscle coat at some distance from the inflamed stricture. The operative procedure is illustrated in *Fig.* 2.

At the original operations which were done in 1967 efforts were made to confine the myotomy to the longitudinal muscle as it was feared that diverticulum or rupture of the oesophagus might occur if both muscle layers were divided. It was found that by the time it was possible to be certain that the longitudinal muscle layer had been completely divided the mucosa was often visible. During the past 3 years both muscle coats have been divided as not only does this not appear to give rise to complications but also it allows better retraction of the cut ends. As the muscle retracts a tube of bare mucosa about 1·5–2 cm. in length is left exposed.

FIG. 1.—A, The normal action of the longitudinal muscle on the oesophagogastric junction. B, The manner in which it is suggested that the longitudinal muscle acts after it has been divided transversely.

After myotomy the hernia is repaired by Hill's (1967) method.

On two occasions a double myotomy was done with division of the muscle layers just above the stricture and again just below the aortic arch. This is not our normal practice. It is of interest that although in both patients the oesophagus was mobilized up to the aortic arch the blood-supply to the portion of oesophagus between the myotomies remained adequate.

ANALYSIS OF CASE RECORDS

Circumferential myotomy has been combined with hernial repair in 26 patients during a period of 4 years. The sex incidence of the patients was equal. Their average age was 58 years.

In 7 of the earlier patients Allison's method of repair was used (Allison, 1951). In all but 1 of the patients operated on in the past 2½ years the method of repair described by Hill (1967) has been employed.

Vagotomy and a gastric drainage operation were added in 10 patients. The commonest reason for vagotomy was to allow easier reduction of the hernia (5 patients). In 2 patients it was done because of a pathologic condition of the pylorus and in 3 patients both of these indications for vagotomy were present.

Nineteen patients had a peptic stricture. There must be differences of opinion on occasion as to whether or not the lesion is a true stricture. The diagnosis was made on the radiological appearances, the oesophagoscopic findings with obstruction to the passage of bougies, and, at operation, the arrest of a stomach tube passed down the oesophagus.

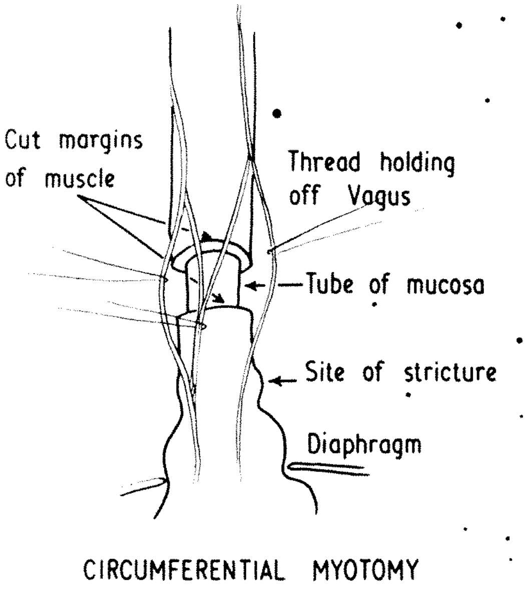

FIG. 2.—A diagrammatic representation of the operative procedure.

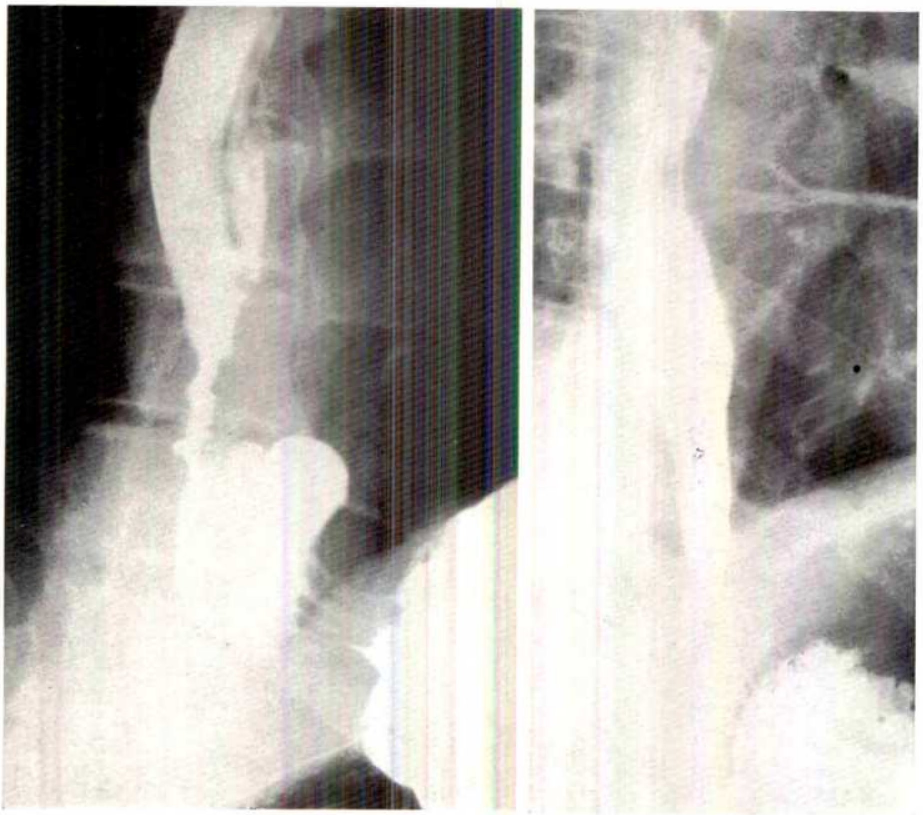
In 14 patients the stricture was described at oesophagoscopy as being soft and inflamed. More often than not there was acute oesophagitis above it. Oesophageal biopsies showed chronic inflammatory infiltration or evidence of mucosal ulceration. In 2 patients the stricture felt hard and became increasingly difficult to dilate. One such stricture had developed after an operation for diverticulitis. In 3 patients the stricture was associated with a penetrating ulcer and biopsies showed either granulation tissue or part of an ulcer base.

The common findings at thoracotomy were those of a thickened area in the oesophageal wall either extending from the oesophagogastric junction for a varying distance upwards or with its lower limit just above the junction. In most of the patients with a stricture there was peri-oesophagitis with enlarged mediastinal glands. In 8 patients the degree of peri-oesophagitis was such as to make mobilization of the oesophagus tedious.

The average distance of the stricture from the upper incisor teeth as measured at oesophagoscopy was 34 cm. At thoracotomy the stomach tube was commonly held up a short distance above the apparent oesophagogastric junction.

It was usually impossible to decide preoperatively from the radiological and oesophagoscopic findings if the hernia was reducible. The decision had to be made at operation.

In 5 patients there was no stricture but the hernia was difficult to reduce, and in 1 female patient myotomy was added to hernial repair as she had severe aerophagy. On radiographic screening frequent upward jerking movements of the cardia were seen with each eructation. The aerophagy was so bad that, according to her husband, she kept swallowing flies if he took her for a walk on a summer's evening.



A B

FIG. 3.—*Case* 1. A, Preoperative barium-swallow film, showing a hiatal hernia and stricture. B, Postoperative barium-swallow film.

The following representative case records are illustrative of various types of lesion dealt with, namely, strictures at or near the cardia, postoperative stricture, stenosis with a penetrating ulcer, and sliding hernia uncomplicated by stricture.

1. Strictures at or near the Cardia.—

Case 1.—J. H., a man aged 55 years. This patient who was first seen in 1967 gave a 3-year history of intermittent dysphagia and episodes of food impaction. The dysphagia had become worse in the previous 6 months. The barium-swallow film is shown in *Fig.* 3 A. At oesophagoscopy there was a soft, irregular stricture at 36 cm. A biopsy from it showed granulation tissue. Towards the end of 1969 the patient began to have pain in addition to dysphagia and an operation was performed on 4 March, 1970. There was a thickened, rather firm segment of oesophagus about 3 cm. in length with its lower limit 2 cm. above the cardia. Peri-oesophagitis was present. The oesophagus was mobilized up to the aortic arch. The vagi, which were embedded in the thickened oesophageal wall, were divided and pyloromyotomy was done. The muscle coats were divided above the stricture. The hernia was repaired by Hill's method. *Fig.* 3 B shows the postoperative barium-swallow film. The cardia appeared to be competent. At postoperative oesophagoscopy there was no stricture to be seen. During the follow-up of 17 months the patient has remained free from symptoms.

Case 2.—M. C., a woman aged 57 years. This patient had a 14-month history of dysphagia. The barium-swallow film is shown in *Fig.* 4 A. At oesophagoscopy there was a soft, inflamed, bleeding stricture at 34 cm. A biopsy showed patchy ulceration of the mucosa with mixed inflammatory infiltrate at the squamocolumnar junction. At operation on 28 April, 1970, there was a sliding hiatal hernia and about 2·5 cm. above the cardia there was a thickened segment of oesophagus 2·5 cm. in length. A moderate amount of peri-oesophagitis with enlarged mediastinal glands was noticed. The hernia was difficult to reduce. Myotomy of both muscle layers was done above the stricture. The vagi were preserved and pyloromyotomy was carried out. The hernia was repaired by Hill's method. *Fig.* 4 B shows the postoperative barium-swallow film. Reflux could not be produced. At oesophagoscopy there was no evidence of stricture or of oesophagitis. During a follow-up of 16 months the patient has remained free from symptoms.

2. Postoperative Peptic Stricture.—

Case 3.—A. C., a man of 60 years. This patient had been known to have a hiatal hernia for 10 years. He developed dysphagia 2 weeks after an operation for diverticulitis. *Fig.* 5 A shows the barium-swallow film. In 1967

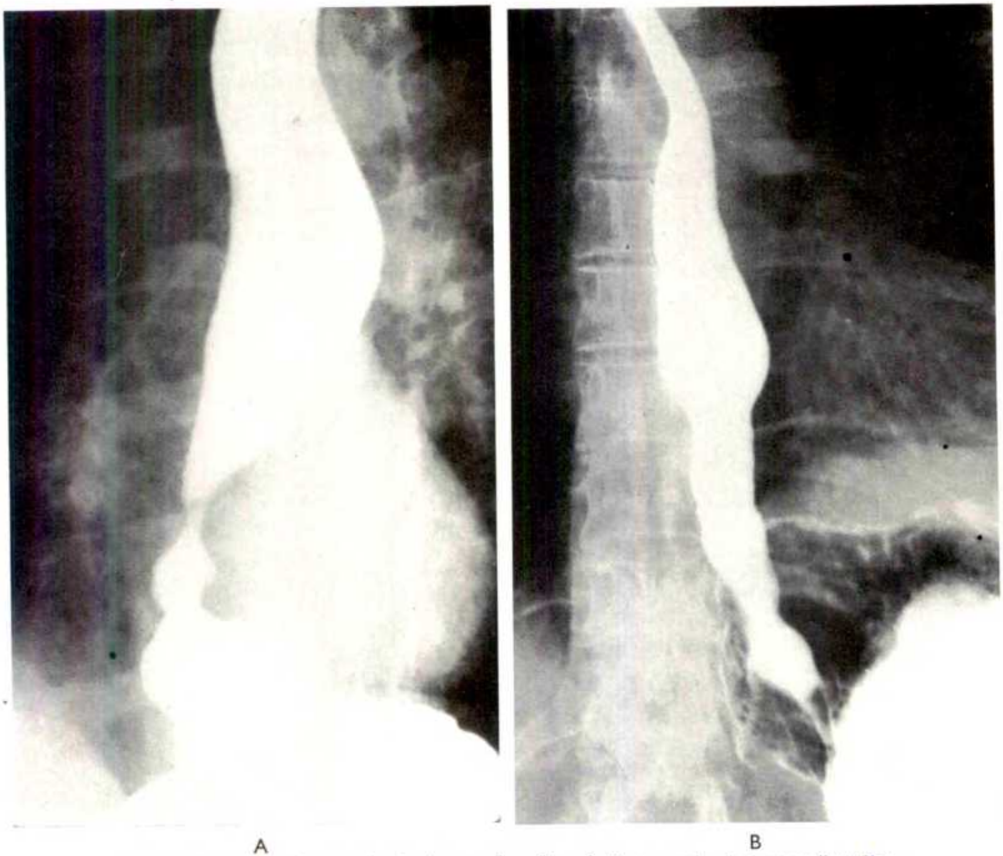


FIG. 4.—*Case* 2. A, Preoperative barium-swallow film. B, Postoperative barium-swallow film.

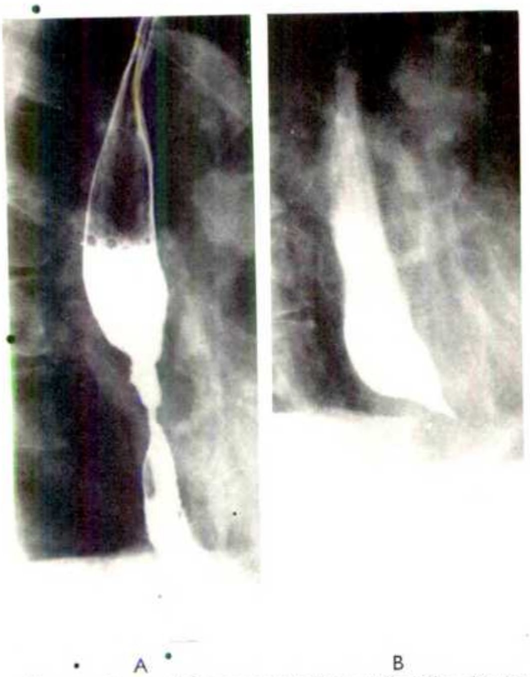

FIG. 5.—*Case* 3. A, Preoperative barium-swallow film, showing a stricture which developed after an operation for diverticulitis. B, Postoperative barium-swallow film.

an inflamed stricture at 38 cm. was noted. Oesophagoscopy was carried out twice during the next 3 months and the stricture became harder and more difficult to dilate. At operation in February, 1968, a sliding hernia was found. The oesophagus was thickened and hard at and above the cardia. It was mobilized with a good deal of difficulty. Myotomy was done just above the stricture and again just below the aortic arch together with vagotomy and pyloromyotomy. *Fig.* 5 B shows the postoperative barium-swallow film. At oesophagoscopy there is now a smooth narrowing at the lower end of the oesophagus. During the past 3½ years the patient has put on weight and has kept well apart from occasional slight dysphagia.

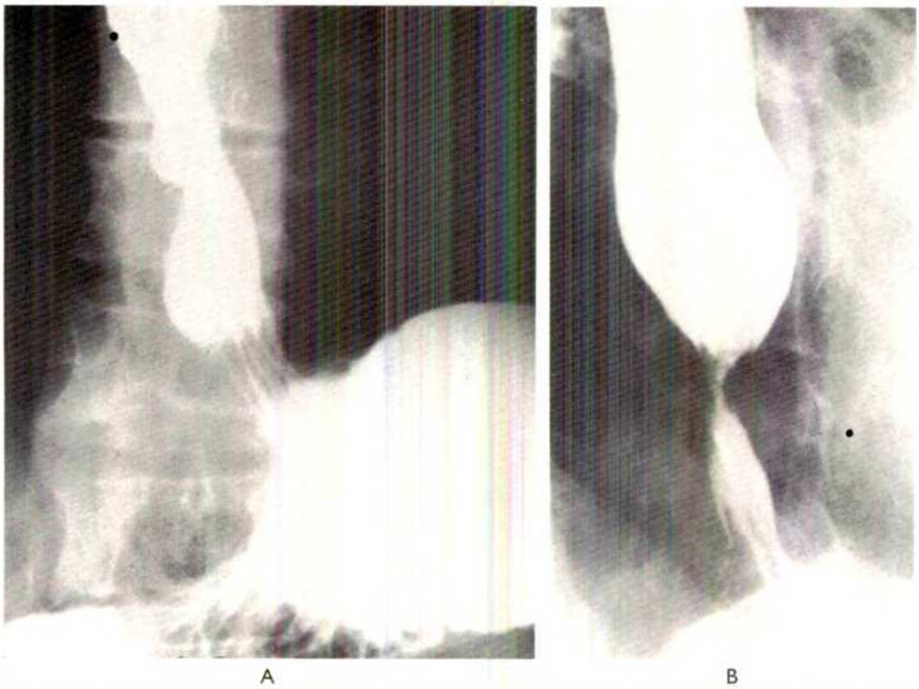
3. Penetrating Ulcer.—

Case 4.—F. P., a man of 57 years with a history of varying degrees of dysphagia for 7 years. *Fig.* 6 A shows the barium-swallow film denoting a penetrating ulcer at the stricture. There was also cicatricial contracture of the duodenum. At oesophagoscopy in 1967 an inflamed, ulcerated stricture at 35 cm. was found. Endoscopy was repeated in 1968 and 1969 with the same findings. Operation was carried out in March, 1969. The oesophagus was difficult to mobilize. It felt thickened up to the aortic arch with a hard area a short distance above the cardia. There was a small sliding hernia. The vagi, which were embedded in the oesophageal wall, were divided and a gastrojejunostomy was performed. The oesophageal muscle was divided transversely just above the hard area and again just below the aortic arch. The hernia was repaired by Hill's method.

Temporary improvement followed but severe dysphagia recurred owing to a tight, hard, fibrous stricture which is shown in *Fig.* 6 B. At a second operation 5 months later no hernia could be seen. A stomach tube was held up 3 cm. above the hiatus. The lower part of the oesophagus was resected with interposition of a jejunal segment between the oesophagus and the stomach. Histological examination showed a healed ulcer deep to which there was dense fibrosis extending through all coats of the oesophagus. Healing was by squamous epithelium.

The patient has remained well for 2 years.

Case 5.—N. W., a woman aged 67 years, had been known to have a hiatal hernia for 6 years. When seen in 1970 her symptoms had become worse and she had a great deal of pain and dysphagia. The barium-swallow film is shown in *Fig.* 7 A. Oesophagoscopy showed a stricture with a hard ulcer on the posterior wall lying at 36 cm. A biopsy from the region of the ulcer contained columnar epithelium. At operation on 28 July, 1970, a sliding hernia was found and the oesophagus felt hard,



A B

FIG. 6.—*Case* 4. A, Preoperative barium-swallow film, showing a penetrating ulcer at the site of the stricture. B, Postoperative barium-swallow film, showing the presence of a tight fibrous stricture following healing of the penetrating ulcer.

FIG. 7.—*Case* 5. A, Preoperative barium-swallow film, showing a peptic stricture with a penetrating ulcer. B, Postoperative barium-swallow films, showing healing of the ulcer and disappearance of the stricture. Some reflux persists.

above the cardia. There was a palpable ulcer with a dimple on the external surface of the oesophagus at the ulcer base. Enlarged glands were noted in the adjacent mediastinum. Thickening of the oesophagus extended upwards to just above the level of the inferior pulmonary vein. The hernia was difficult to reduce. Myotomy was done above the stricture together with vagotomy, pyloromyotomy, and hernial repair by Hill's method.

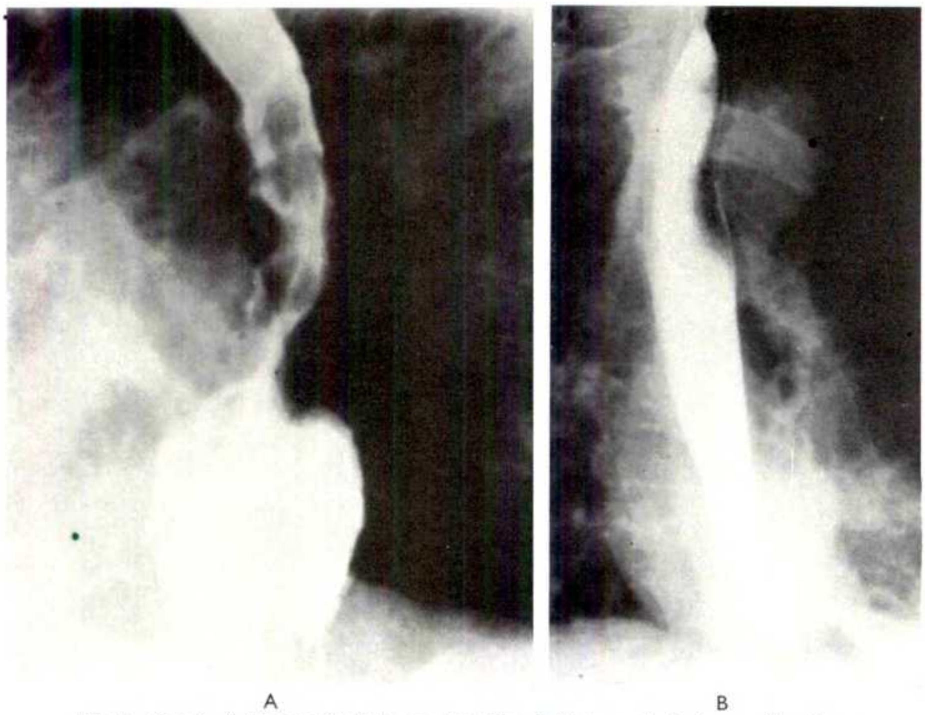

FIG. 8.—*Case* 6. A, Preoperative barium-swallow film. B, Postoperative barium-swallow film.

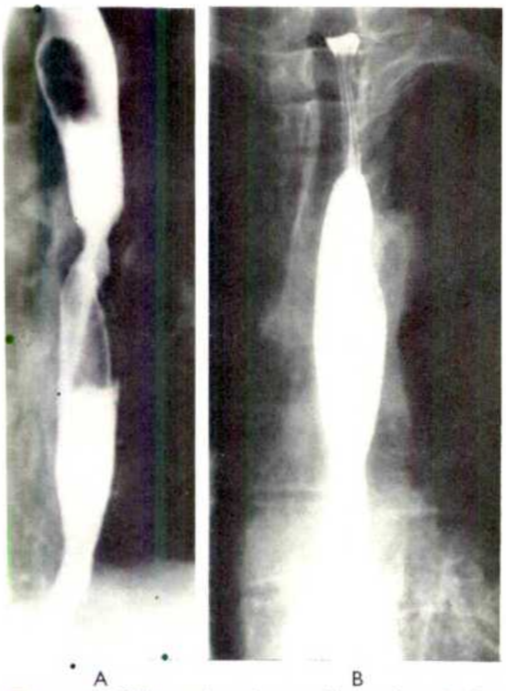

FIG. 9.—A, High peptic stricture with an ulcer. B, Postoperative barium-swallow film, showing a slight residual stenosis.

Fig. 7 B shows postoperative barium-swallow films. It is still possible to produce some reflux of barium. At oesophagoscopy the ulcer is no longer visible and there is no sign of stricture.

During follow-up of 1 year the patient has remained free from symptoms.

4. Sliding Hernia uncomplicated by Stricture but difficult to reduce.—

Case 6.—W. S., a man of 62 years with a long history of heartburn and regurgitation, repeated laryngitis, pneumonitis, pleurisy, and chronic bronchitis. The barium-swallow film is shown in *Fig.* 8 A. The distance to the cardia measured 38 cm. at oesophagoscopy. It appeared to be incompetent and there were superficial mucosal erosions above it. At operation the lower part of the oesophagus felt soft and there was no peri-oesophagitis but the hernia was difficult to reduce. The vagi were preserved. Myotomy was done and the hernia was repaired by Allison's method. *Fig.* 8 B shows the postoperative barium-swallow film. During a brief follow-up of 8 months the patient has been free from his previous symptoms but has suffered from post-thoracotomy wound pain.

RESULTS

As the first myotomy in the present series was done in 1967 the follow-up is limited. In some of the earlier patients postoperative oesophagoscopy was not done.

In 14 patients with soft, inflamed strictures the symptomatic results were good. In 2 of them some reflux could still be produced by the radiologist.

Where postoperative oesophagoscopy was done (7 patients) a smooth, soft, residual narrowing insufficient to cause dysphagia was seen in 1 patient. In the others no stenosis was visible.

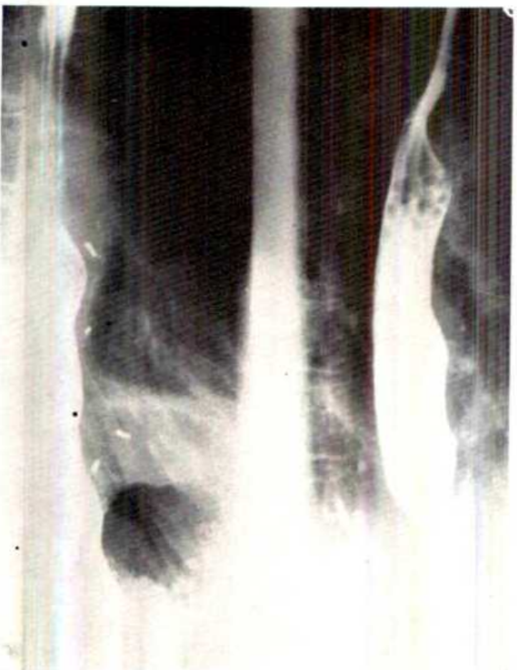

FIG. 10.—The left-hand barium-swallow film shows four markers. The upper two are on the cut ends of muscle, the lowest one is on the oesophagogastric junction, and the one immediately above it is on the hiatal margin. This film shows the characteristic 'wiped-joint' appearance caused by mucosal bulging at the myotomy. The bulging, which is present in certain phases of swallowing only, is less marked on the right-hand film.

In 1 patient with a postoperative stricture the symptomatic result was good but a moderate smooth stenosis is still to be seen at endoscopy.

Of 3 patients with a penetrating ulcer, 2 were complete failures. In both of the failures the ulcer healed with squamous epithelium, leaving a tight fibrous stricture. The other patient has a good symptomatic result but reflux is still seen on screening. In spite of this the ulcer and stricture are no longer visible.

In 1 patient with a high ulcerated stricture (*Fig.* 9 A) where myotomy was done below the lesion the ulcer healed leaving a very slight soft stenosis which was visible both radiologically (*Fig.* 9 B) and at oesophagoscopy but which was insufficient to cause dysphagia.

The patients with uncomplicated hernia which were difficult to reduce all had good symptomatic and radiological results.

The patient with severe aerophagy lost her previous heartburn and now swallows air only very occasionally.

Postoperative Radiological Appearances.—After circumferential myotomy the radiological appearances are both novel and interesting. In order to make it easier to identify the landmarks Cushing clips were placed on the cut ends of muscle, on the margin of the hiatus, and on the oesophagogastric junction.

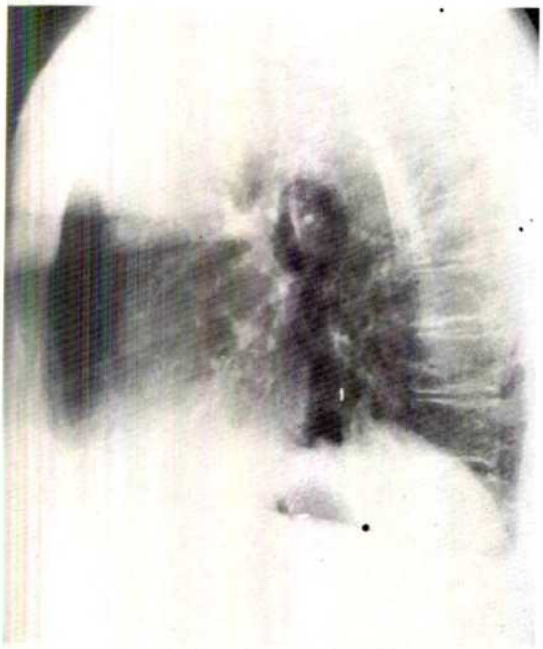

FIG. 11.—This film shows three markers. The upper two are on the cut ends of muscle and the lowest one is on the hiatal margin. The myotomy markers are 3 cm. apart in this patient.

The characteristic appearance is that of a smooth bulging which the markers show to be at the site of myotomy (*Fig.* 10). It has the appearance of a plumber's 'wiped joint', it is present in certain phases of swallowing only, and it has not been observed to increase in size with the passage of time.

The cut ends of muscle separate for a distance of 2–3 cm. (*Fig.* 11). In 1 patient the myotomy markers remained closer together (*Fig.* 12). This is unusual. If there is any subsequent change in the relative positions of the myotomy markers it is in the direction of further slight separation.

No hold up of barium can be detected as a result of the myotomy, which is in accord with the fact that where the stricture has been cured the patient has no dysphagia.

It has been possible to perform cineradiography in only 2 patients. It was observed that during swallowing there was an upward movement of the upper myotomy marker increasing its distance from the lower myotomy marker while the latter maintained a constant relation to the marker on the hiatal margin. The relative position of the markers in two phases of swallow is shown in *Fig.* 13. These findings suggest that contraction of the longitudinal muscle is causing distraction at the myotomy rather than an upward pull on the cardia.

The postoperative films in the successful cases show disappearance of the stricture with satisfactory reduction of the hernia and with a good angle between the fundus and the oesophagus.

Indications.—The successful treatment of peptic stricture by hernial repair depends on the possibility of adequate reduction of the hernia with a low recurrence rate and also on the pathological changes in the oesophagus being reversible. A decision on both of these aspects must be a matter of experience and judgement.

Circumferential myotomy makes reduction of the hernia possible in some patients where there would otherwise be undue tension on the oesophagus. It must be emphasized that it is effective only in borderline cases and that its indications are strictly limited.

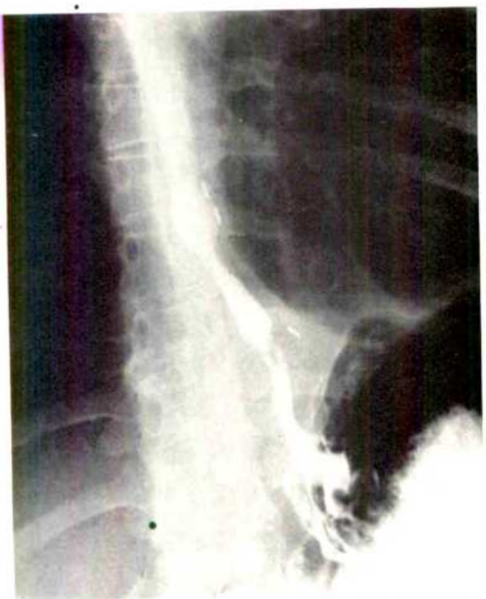

FIG. 12.—A film showing a less common situation where the myotomy markers have remained relatively close together. The position of the lower two markers shows that the oesophagogastric junction is lying well below hiatal level.

It is not indicated in the following circumstances:

1. Where there is a long area of total mucosal loss with gross changes in the oesophageal wall and peri-oesophageal tissues, the hernia is obviously irreducible and the limited effect of myotomy will not alter the situation.

2. Penetrating ulcer. Although 1 patient with a penetrating ulcer did well, 2 were total failures. A penetrating ulcer is considered to be a contra-indication to myotomy and hernial repair.

3. Postoperative peptic stricture. Although the 1 patient with a postoperative stricture did well it is probable that this type of lesion is often irreversible. Postoperative strictures are usually associated with changes involving all the coats of the oesophageal wall (Davidson, 1967b).

DISCUSSION

After Heller's longitudinal myotomy, diverticulum formation or oesophageal rupture is not a hazard. So far it would seem that a transverse myotomy is also a safe procedure. Unlike Heller's operation or the more extended longitudinal myotomy used in the treatment of diffuse muscle spasm of the oesophagus, after circumferential myotomy there is an obvious bulging of the mucosa, as seen in certain phases of swallowing on the barium-swallow film. This weakened area has not given rise to complications. On two occasions where a second thoracotomy was done there was nothing to suggest the presence of a weak area likely to give rise to a diverticulum or to rupture.

Manometric and motility studies have not been done. They may prove interesting both in connexion with the effect of the myotomy on the distal part of the oesophagus and the mechanism of the passage of food along the oesophagus after interruption of the muscle coat.

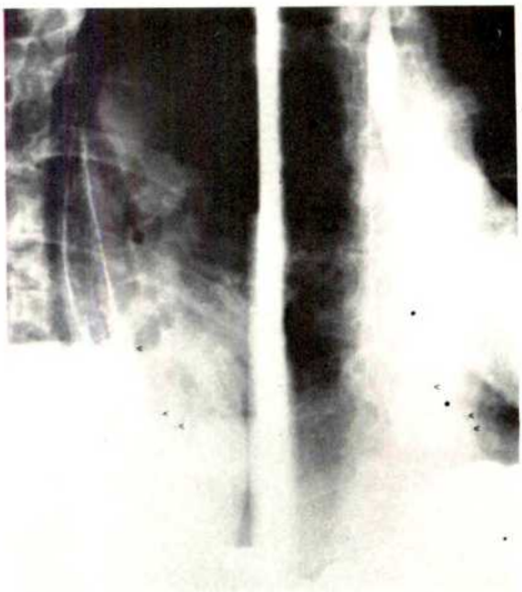

FIG. 13.—Two films in different phases of swallowing. During swallowing the upper myotomy marker has moved upwards on the left-hand film while the lower myotomy marker remains in the same relative position to the hiatal margin in both films. This suggests that contraction of the longitudinal muscle is causing distraction of the cut ends of muscle rather than exerting a direct upward pull on the cardia.

Does myotomy serve any useful function? It may be that all our patients with or without a peptic stricture who were successfully treated by myotomy and hernial repair could have been dealt with just as well by hernial repair alone. This is difficult to prove or disprove. The problem is further complicated by the fact that in a number of cases vagotomy and a drainage procedure were also done and the improvement could be attributed to such measures. All that can be said at this stage is that the results with the addition of myotomy seem better than those previously obtained by us in similar cases. The fact that myotomy results in a little measurable elongation of the oesophagus, that a taut oesophagus becomes less so after myotomy, and that muscle contraction appears to cause distraction at the site of myotomy rather than an upward pull on the cardia suggests that it is a rational procedure in properly selected cases.

The number of cases of peptic stricture seen by any one surgeon is not large and the number suitable for circumferential myotomy is much smaller still. It is difficult for any individual surgeon to gain adequate experience of the procedure. Although 26 patients have had this operation over a period of 4 years this number includes at least 5 where hernial repair would not now be attempted. It has been necessary to exceed the indications for the operation in order to learn both its virtues and its limitations.

So far transverse myotomy has been used mainly in the treatment of stricture. The importance of contraction of the longitudinal muscle of the oesophagus in relation to hiatal hernia has not yet been assessed. Whether or not there is a place for myotomy, especially of the longitudinal muscle, in the surgery of hiatal hernia uncomplicated by stricture is not known. It is suggested that this is a field for further study.

GLOMUS JUGULARE TUMOURS—RADIOTHERAPY OR SURGERY?

BY G. W. GLOVER AND J. BLOCK

DEPARTMENTS OF OTOLARYNGOLOGY AND SURGICAL NEUROLOGY, UNIVERSITY OF DUNDEE AND DUNDEE ROYAL INFIRMARY, DUNDEE

SUMMARY

Seven patients with glomus tumours are described. Many authors still advocate surgery for these tumours, despite the excellent results obtained with radiotherapy. The results obtained by irradiation in the present series strongly support the view that it is the treatment of choice in large petrosal tumours and those with intracranial extension.

THE glomus jugulare was first described by Guild (1941) as a tiny structure situated in the adventitia of the dome of the jugular bulb. It is a small ovoid body, measuring approximately 0·5 × 0·25 mm., and several similar structures may be associated with the tympanic branch of the glossopharyngeal nerve and with the auricular branch of the vagus. When present in the middle ear, usually in association with the tympanic plexus, the structure is known as the glomus tympanicum. These glomus bodies are all histologically identical with other chemoreceptor tissues, such as the carotid body and the aortic body.

Rosenwasser (1945), in describing a vascular tumour arising in the hypotympanum and histologically resembling the carotid body, suggested that it had originated in the glomus jugulare. Since this first case many series have been reported and the glomus jugulare tumour is now recognized as the commonest tumour of the middle ear. From a pathological point of view tumours of the chemoreceptor tissues arising at any site appear to be identical. It has become customary to refer to them as chemodectomas or non-chromaffin paragangliomas.

The original concept of treatment of glomus jugulare tumours was conditioned by the fact that the previously well-documented carotid body chemodectoma was considered to be radio-resistant. It is the purpose of this paper to demonstrate the role that radiotherapy can play in the management of these tumours and to confirm its superiority over surgery in the large petrosal and extra-petrosal tumours with intracranial extension.

CASE REPORTS

Case 1.—W. R., male, born in 1921. This patient had a radical mastoidectomy in 1942 for a discharging left ear. Postoperatively he developed a total left-sided facial palsy which recovered gradually over the next 9 months. In 1944 the ear was re-explored because of severe pain and a biopsy was reported then as showing an 'angio-endothelioma'. He again developed a postoperative facial palsy which never recovered completely. Postoperatively he received a course of irradiation to a total of 1250 r.

He remained well until 1953, when he presented to a neurosurgical unit complaining of sudden weakness in all four limbs, unsteadiness, dysphagia, and hoarseness. He was noted to have papilloedema, a gross nystagmus slow to the left, paralysis of the left seventh, eighth, ninth, and tenth cranial nerves, and left-sided ataxia. A pink granulomatous lesion was present in the floor of the left external auditory meatus. His condition suddenly deteriorated with grave respiratory embarrassment, and cerebellar decompression was necessary. At operation (Professor Norman M. Dott) a severe foraminal herniation was found with gross displacement of the contents of the posterior fossa by a large mass situated anteriorly on the left side. The lesion was so vascular and the cerebellum so tight that it was not possible to approach the tumour for a biopsy to be taken without the risk of a catastrophic haemorrhage. A biopsy was finally taken via the external auditory meatus from the middle-ear region, and this time histological examination showed the typical features of a tumour of the glomus jugulare.

Postoperatively, although the patient's foraminal impaction had been relieved his other neurological signs were not significantly changed. Three weeks later he received a radical course of radiotherapy, a maximum skin dose of 4000 r and a minimum tumour dose of 3425 r being delivered over a period of 4 weeks. Thereafter his symptoms gradually improved and his papilloedema resolved. By 1955 he was working full-time without undue difficulty.

At present the patient still has a total left-sided facial palsy and impairment of the eighth, ninth, tenth, and eleventh cranial nerves. There are no granulations in the ear, the mastoid cavity being sealed off by a false membrane. Tomography (*Fig.* 1) shows sclerosis of the partially destroyed petrous bone on the left.

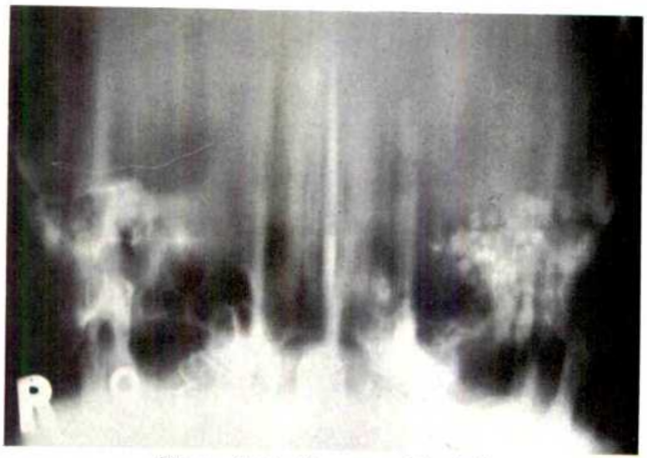

FIG. 1.—*Case* 1. Tomogram of the skull.

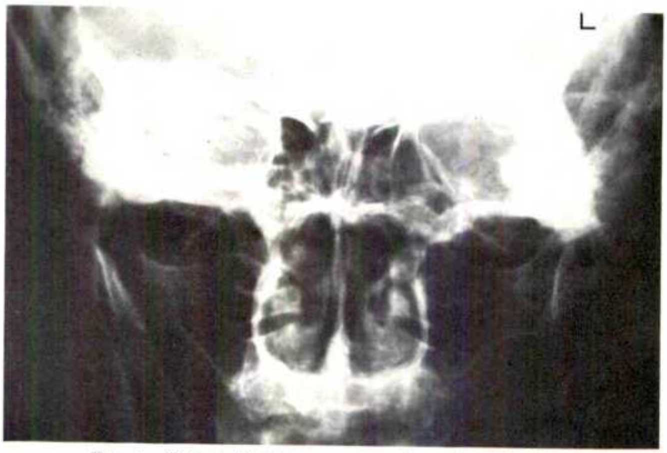

FIG. 2.—*Case* 2. Posterior-anterior radiograph of the skull.

Case 2.—M. C., female, born in 1915. This patient's symptoms began in 1942 with pain in the left side of the face and a feeling of fullness in the left ear. Unilateral deafness was noted in 1947 in association with a large polypus in the meatus and slight weakness of the left side of the face. Radical mastoidectomy in 1948 was accompanied by profuse haemorrhage. Histology of the removed tissue was reported as 'granulations of a chronic inflammatory type'.

By 1955 the pain and weakness of the face had increased and the patient developed dysphagia, hoarseness, persistent tinnitus, and a tendency to fall to the left. There was a large pulsatile mass in the left parapharyngeal space bulging the lateral wall of the pharynx. She now had total impairment of the seventh to twelfth cranial nerves on the left side. Radiographs showed gross enlargement of the foramen lacerum which had enlarged partly at the expense of the tip of the petrous temporal bone and partly at the expense of the greater wing of the sphenoid. The foramen ovale was also enlarged. This is shown on the radiograph published in a previous report on this patient (Stewart, Ogilvie, and Sammon, 1956). The biopsy taken in 1948 was reviewed at this stage and was now reported as showing a glomus jugulare tumour. She was given a radical course of radiotherapy with a tumour dose of 3920 r in 4 weeks and a maximum skin dose of 4750 r. Following therapy the pulsatile mass vanished.

The patient has been in good health since the course of radiotherapy and her only symptoms at present are persistent tinnitus in the left ear, slight pain in the face, and a tendency to fall occasionally to the left. The facial palsy has partly recovered but there is still total impairment of the other cranial nerves affected. There is no evidence of tumour clinically and the mastoid cavity is dry and healthy. Radiographs of the skull show considerable erosion of the petrous temporal and adjacent floor of the middle fossa (*Figs.* 2 and 3) and this is confirmed by tomography.

Case 3.—M. L., female, born in 1921. This patient was first seen in 1955 with left-sided deafness and tinnitus and an episode of hoarseness and dysphagia. At that time she was found to have a paralysed left vocal cord and a non-functioning left ear. She was kept under observation until 1960 when she was referred to a neurosurgical unit. In addition to the above findings she had now developed a horizontal nystagmus, loss of sensation on the left side including the face, and a mild spastic hemiparesis with impaired co-ordination on that side. Tomograms of the internal auditory meati were normal. Myodil ventriculography showed a displacement of the aqueduct and the fourth ventricle to the right. A posterior fossa exploration was carried out and a tumour was found in the left cerebellopontine angle. Only a subtotal removal could be achieved because of the close application of the tumour to the brain-stem and the ninth and tenth cranial nerves. Histological examination proved it to be a tumour of the glomus jugulare.

The patient's subsequent progress was marred by bizarre symptomatology, such as tinnitus with lateral gaze to the left and a gross disturbance of balance which was mostly functional.

In 1966 a red blush was noted behind the postero-inferior quadrant of the left tympanic membrane. A subtraction vertebral angiogram (*Fig.* 4) showed the tumour circulation postero-inferiorly to the petrous apex. A radical course of radiotherapy was given on the linear accelerator: 4940 r in 20 treatments.

The patient remains well despite her continued functional symptoms, with a much smaller blush still present behind the tympanic membrane. The left vocal cord is still paralysed, there is a mild paresis of the left side of her palate, and there is slight atrophy and weakness of the tongue on the left side.

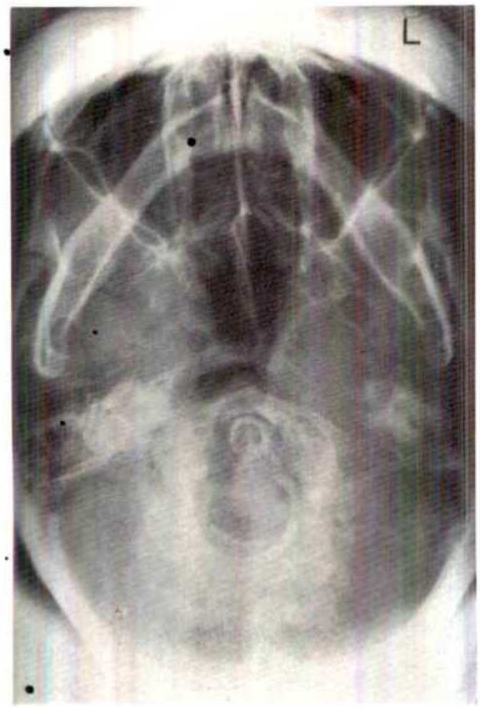

FIG. 3.—*Case* 2. Radiograph of the base of the skull.

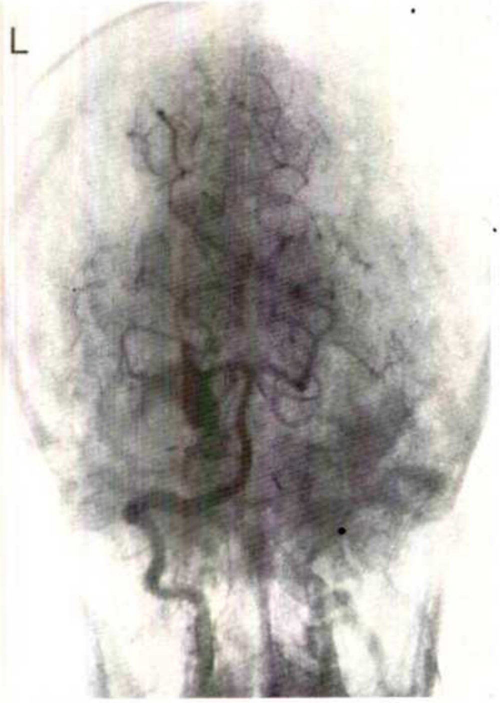

FIG. 4.—*Case* 3. Subtraction vertebral angiogram.

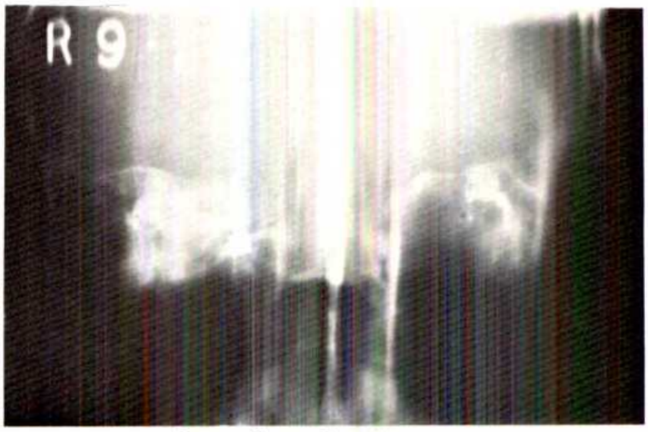

FIG. 5.—*Case* 4. Coronal tomogram.

Case 4.—D. J., female, born in 1947. This patient was admitted in 1961 with acute mastoiditis. Exploration of the mastoid revealed a considerable quantity of pus but excessive haemorrhage requiring transfusion did not permit the operation to be completed. A biopsy of the granulation tissue in the middle ear showed 'the histological appearance of a very vascular fibrous and granular tissue, in part covered by squamous epithelium, and considerable infiltration by chronic inflammatory cells'. Re-exploration 1 week later converted the mastoid and middle ear into a modified radical mastoid cavity and once again profuse haemorrhage was encountered and transfusion was necessary.

In 1963 the patient presented with spontaneous haemorrhage from the left ear, a peripheral facial paresis, and wasting of the left side of the tongue. Coronal tomography (*Fig.* 5) showed an extensive destructive lesion in the left petrous extending to the apex and obliterating the internal auditory meatus. Left carotid and vertebral angiograms showed the bulk of the blood-supply arising from branches of the vertebral axis and virtually no filling from either the internal or the external carotid. A biopsy of the tissue within the mastoid cavity showed the characteristics of a glomus jugulare tumour. A radical course of radiotherapy was given on the linear accelerator, 5500 r being delivered by a combination of wedge fields and a direct lateral field.

At the present time the patient is symptom-free and there is no evidence of the tumour. She has a residual left facial and hypoglossal palsy and total deafness. Surprisingly, the vocal cords and palate move normally.

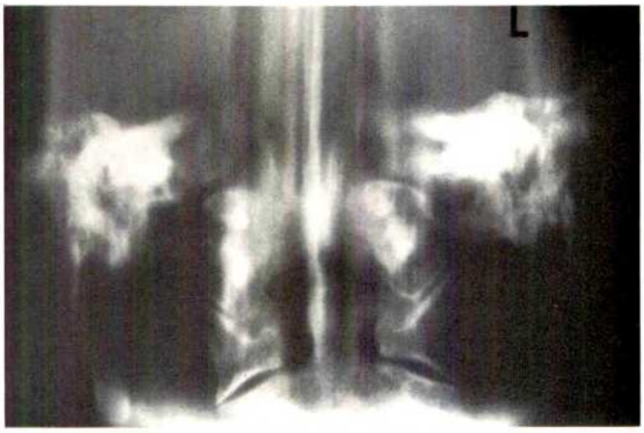

FIG. 6.—*Case* 5. Coronal tomogram.

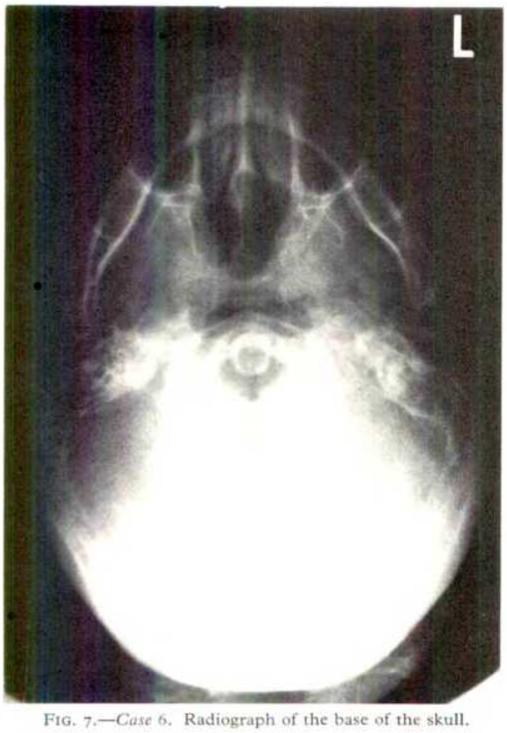

FIG. 7.—*Case* 6. Radiograph of the base of the skull.

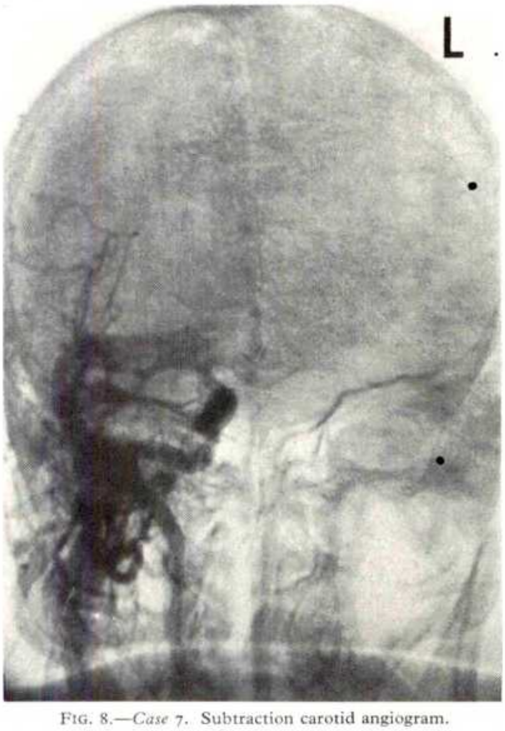

FIG. 8.—*Case* 7. Subtraction carotid angiogram.

Case 5.—I. M., female, born in 1893. This patient presented in 1963 with a short history of right-sided pulsing tinnitus. A red blush was noted behind the tympanic membrane. The cranial nerves were intact. Coronal tomography (*Fig.* 6) showed erosion of the apex of the petrous bone and expansion of the internal auditory meatus.

A biopsy was not taken and although radiotherapy was considered it was held in reserve in view of the known slow growth of these tumours and the patient's poor general condition. She was followed for a period of 7 years with little change in the size of the tumour. Her tinnitus continued unabated without any cranial nerve involvement. She died of unrelated causes in 1970.

Case 6.—C. C., female, born in 1896. This patient attended in 1964 with a 6-week history of hoarseness and left-sided deafness. She had a paralysed left vocal cord and the left tympanic membrane was of a uniform pink colour. A submentovertical radiograph (*Fig.* 7) showed a small defect of the petrous apex and adjacent bone in the region of the jugular foramen.

A tympanotomy was carried out and a biopsy taken. This showed a tumour of the glomus jugulare. A radical course of radiotherapy was then given on the linear accelerator, 5500 r being delivered by wedge fields over 4 weeks. The patient was followed over the next 6 years and showed no progression of the neurological features. The pink colour of the tympanic membrane persisted. The patient died in 1969 of an unrelated complaint. At post-mortem examination a large asymptomatic acoustic neuroma was present on the same side as the glomus jugulare tumour and she was also found to have a small frontal meningioma.

Table I.—ANALYSIS OF THE CASES IN THE PRESENT SERIES

CASE NO.	AGE AT ONSET OF SYMPTOMS (yr.)	SEX	CRANIAL NERVES INVOLVED	TREATMENT	RESULTS OF TREATMENT	PERIOD ELAPSED SINCE ONSET OF SYMPTOMS (yr.)	PERIOD OF FOLLOW-UP AFTER IRRADIATION (yr.)
1	21	M.	VII, VIII, IX, X, XI	Mastoidectomy, craniotomy, irradiation	+ + +	29	18
2	27	F.	VII, VIII, IX, X, XI, XII	Mastoidectomy, irradiation	+ + +	29	16
3	34	F.	VIII, IX, X, XI, XII	Craniotomy, irradiation	+ +	16	5
4	14	F.	VII, VIII, XII	Mastoidectomy, irradiation	+ + +	10	8
5	70	F.	—	Nil	+	6*	—
6	68	F.	IX, X, XI	Tympanotomy, irradiation	+ +	5*	5
7	62	F.	VII, VIII, IX, X, XI, XII	Irradiation	+ + +	1	1

+ + +, No visible sign of tumour; + +, regression in size; +, no change.

* Died of unrelated causes.

Case 7.—A. B., female, born in 1908. This patient presented in 1970 with a 3-month history of progressive right-sided deafness and pain in the right side of the face and right ear. She also complained of unsteadiness. Examination showed papilloedema, a partial right facial palsy, and total impairment of the eighth to twelfth cranial nerves. The tympanic membrane was bright red and there was a loud bruit over the right temporal region. There were, in fact, no cerebellar signs.

Plain radiographs of the skull followed by tomography in the occipito-mental and coronal planes showed extensive destruction of the occipital bone around the jugular foramen, the apex of the petrous in the region of the internal auditory meatus, and the sphenoid near the foramen lacerum and the foramen ovale. Carotid angiography (*Fig.* 8) showed the tumour filling rapidly and acting as an arteriovenous shunt; in the arterial phase there is already filling of the right sigmoid and transverse sinus.

The diagnosis of a glomus jugulare tumour was a clinical one since it was felt that a biopsy would be too hazardous. The patient was therefore referred for radiotherapy and given a radical course of 5500 r in 4 weeks by the linear accelerator. This was delivered as one lateral and two wedge fields at right-angles. The treatment was given to a block of tissue which included the whole of the petrous temporal bone, the greater wing of the sphenoid in front, and part of the occipital bone behind. Following this there was considerable objective improvement in the clinical features. The facial palsy showed almost total recovery, the bruit disappeared, and the papilloedema resolved completely. The functions of the last four cranial nerves show no sign of improvement.

ANALYSIS OF CASES

The series is summarized in *Table I*. Of the 7 patients, 6 had tumours of the glomus jugulare and 1 a tumour of the glomus tympanicum (*Case* 5).

In 5 of these 7 patients surgery was undertaken for various reasons but removal was incomplete and was followed by radiotherapy. Attempted removal by posterior fossa exploration was unsuccessful in 2 of the 5 cases, and removal by mastoidectomy was inadequate in a further 2 patients. One patient received radiotherapy following a positive biopsy at tympanotomy, and 1 patient was irradiated without biopsy, the diagnosis being made on clinical and radiological grounds. The patient with the tumour of the glomus tympanicum had neither surgery nor radiotherapy. Of the 6 patients given radiotherapy, 5 are still alive and well without evidence of progression of the tumour at periods ranging from 1 to 18 years following irradiation; the other died of unrelated causes.

Six of the 7 patients had multiple cranial nerve palsies implying intracranial extension, together with radiographic evidence of bone erosion. Although improvement in the cranial nerve palsies has been minimal, the striking feature has been the improvement in the intracranial hypertension in the 2 cases where this was a feature. In 1 of these (*Case* 1) the patient was *in extremis*; surgical decompression of the posterior fossa provided a respite to allow radiotherapy to take effect. In the second patient (*Case* 7) the condition was not as serious and the papilloedema resolved with radiotherapy alone.

DISCUSSION

It has been claimed that the blood-supply of these tumours arises from the ascending pharyngeal branch of the external carotid artery (Kempe, 1970). However, a supply from the vertebrobasilar system has been reported (Farrell and Hawkins, 1967; Lauren, 1968). In both the patients in our series where vertebral angiography was done (*Cases* 3 and 4) there was a significant supply from the vertebral system. Plain radiography, tomography, and detailed angiographic mapping, including if possible differential carotid angiography, vertebral angiography, and retrograde jugular phlebography, would be invaluable guides in assessing tumour size and planning the best fields for radiotherapy.

The treatment of glomus jugulare tumours will naturally depend on factors such as the patient's symptoms, age, and general condition. Apart from these features, the treatment will be dictated by the size of the tumour at the time of diagnosis, the amount of destruction that it has produced both clinically and radiographically, its accessibility, and its vascularity.

It is possible to watch a small blush behind a tympanic membrane for 15–20 years with virtually no change; *Case* 5 was followed for 6 years without progression of the tumour and ultimately died of unrelated causes. Agreement exists that in elderly patients with this kind of tumour or in patients in poor condition it may be justifiable to keep them under regular observation without specific treatment. Where these considerations do not apply it has generally been accepted that slowly growing tumours of the glomus tympanicum are best handled surgically. This has been challenged: Black (1964) states that many believe that in these cases one should proceed to radiotherapy without even biopsy to confirm the diagnosis.

Even greater argument, however, arises over the management of the large petrosal and extra-petrosal tumours. These tumours often show massive destruction radiographically, are extremely vascular, and produce multiple cranial nerve palsies (*Cases* 1, 2, 3, 4, 6, and 7). In a comprehensive review of the management of glomus jugulare tumours Williams, Childs, Parkhill, and Pugh (1955) traced the evolution of the management from the initial enthusiasm for surgery and disillusion with radiotherapy to a final opinion that radical surgery has no place in the treatment, the situation and vascularity of these tumours making any surgical approach extremely hazardous. Their experience with radiotherapy is very satisfactory. This conclusion has been reached by many others (Capps, 1957, 1958; Foote, 1958; Grubb and Lampe, 1965; McCabe and Fletcher, 1967; Rosenwasser, 1967a; Diepeveen, Hentzer, and Rovsing, 1969; Smith, 1970).

Despite these convincing reviews of the effectiveness of radiotherapy many still remain unconvinced. Meacham and Capps (1960) and Thomas, Shaw, and Trowbridge (1960) believe that many of these lesions are surgically resectable, and even though this may require a staged procedure it is preferable to radiotherapy. Ash, Beck, and Wilkes (1964) state that these tumours appear indifferently sensitive to irradiation therapy. Burman (1955) also declares that chemodectomas are entirely radio-resistant. Conley (1970) agrees with the view that the paraganglionic cell is not radio-sensitive and suggests partial resection for decompression, complemented by electro-desiccation in those tumours with multiple cranial palsies. Kempe (1970) is adamant that surgical excision is the treatment of choice and asserts that irradiation is of absolutely no value in glomus jugulare tumours. Curiously, in a more recent article (Kempe, Vanderark, and Smith, 1971) describing his surgical procedure Kempe fails to provide mortality and morbidity figures in support of his radical views.

The advocates of surgery have used the following arguments:—

1. Glomus jugulare tumours are radio-resistant and recurrences occur following irradiation.
2. Irradiation may cause brain necrosis or delayed amyloid degeneration of nervous tissue.
3. The inherent tendency of these tumours to grow slowly exaggerates the reported effectiveness of radiotherapy.

The original concept of radio-resistance arises from early experience with carotid body tumours. These lesions always present with a much larger mass than the glomus jugulare tumours. (The latter, by virtue of their proximity to the lower cranial nerves, manifest themselves when the tumour volume is much smaller.) Radiotherapy is less likely to be effective with the larger carotid body mass. In addition, because these tumours are so much more easily accessible to the surgeon, they are seldom referred for radiotherapy.

The excellent results obtained by radiotherapy, both in this series and others, entirely vitiate the argument of radio-resistance. The tumour is extremely vascular and a relatively small dose of irradiation can produce an endarteritis with obliteration of vessels and a subsequent decrease in the size of the tumour mass. The natural tendency for these tumours to fibrose over the years is thus enhanced by radiotherapy (Schade, 1953). In addition, there is evidence that the tumour cells themselves are sensitive to radiation (Rosenwasser, 1967b).

Recurrences may follow irradiation but this is equally true of surgical removal. When the hazards of surgical removal are considered it is clear that attempts at total excision must often fail owing to the tremendous vascularity and the anatomical site; only the few successful cases are reported.

In fact, there has been no evidence of tumour progression following irradiation in any case in our series.

The dose of irradiation which is needed does not cause tissue necrosis in the central nervous system as has been suggested. Even our patients (*Cases* 1, 2, and 4) who were treated in the days before modern megavoltage therapy experienced no complications and have been followed for periods up to 18 years. Van Miert (1964), in his excellent report, states: 'Megavoltage X-ray therapy in the 4–6 MV. range offers several advantages over 250 kV. X-rays and should give better results. With megavoltage X-rays, because of the clear-cut definition of the beam with very little shading off of dose at the edge, and because of the improved depth-dose obtained, the treated volume can be kept to a minimum. There is considerably less bone absorption, so that a more uniform dose is given to the treated volume and the risk of bone necrosis is negligible. Finally, there is very much less skin reaction. Because of these various factors treatment can be given safely to a considerably higher tumour dose than by conventional X-rays. Properly applied, the morbidity from treatment with 4 MV. X-rays should be nil.' He also advocates a wedge field method of administration in preference to a single lateral field in order to minimize irradiation of the brain-stem.

The third argument against radiotherapy promoted the idea that the inherent slow growth of these tumours would give a misleading impression of its effectiveness. This theoretical argument is controverted by our experience. There is no doubt that in our patients (*Cases* 1, 2, and 7) radiotherapy produced a visibly dramatic improvement with diminution of the tumour mass and resolution of cerebral oedema and papilloedema. There is no visible sign of the tumour in 4 patients (*Cases* 1, 2, 4, and 7) and this is of interest since it was in these patients that the tumour was the most destructive, as seen both clinically and radiologically.

We would still advocate complete surgical excision in the small middle-ear tumours, but surgery for glomus jugulare tumours with intracranial extension and multiple cranial nerve palsies is not justified. Radiotherapy has evolved from its initial palliative application in failed surgery to that of the treatment of choice.

Acknowledgements.—We would like to thank Professor Norman M. Dott, Mr. A. G. Gibb, and Mr. J. K. Brennand for allowing us to report their cases. We are also grateful to the Departments of Radiology and Medical Photography, Dundee Royal Infirmary, for their invaluable help.

ARTERIOVENOUS FISTULAE FOR CHRONIC INTERMITTENT HAEMODIALYSIS: A MODIFIED SURGICAL TECHNIQUE

BY M. HASHMONAI, A. SCHRAMEK, C. CHAIMOVITZ, AND D. ERLIK

DEPARTMENT OF GENERAL AND VASCULAR SURGERY AND DEPARTMENT OF NEPHROLOGY, ABA KHOUSHY SCHOOL OF MEDICINE AND RAMBAM GOVERNMENT HOSPITAL, HAIFA, ISRAEL

SUMMARY

A side-to-end technique for arteriovenous fistulae of the wrist vessels for use in chronic intermittent haemodialysis with venepuncture is proposed. A series of 14 patients in whom this technique has been used is presented. A survey of the different shunting techniques described in the literature is given and their advantages and disadvantages are discussed. The problem of turbulence due to a sharp angulation of the flow through the anastomosis and the possibility of its causing aneurysmata and thrombosis of the fistulae are considered. This problem and its sequelae, together with the problem of the use of the sole remaining artery of the hand when the other has been either occluded or ligated in previous operations, and the possibility of creating an arteriovenous fistula with a vein distant from the artery, are all overcome by this technique.

CHRONIC intermittent haemodialysis is now an established procedure for the treatment of patients in terminal renal failure. This method was introduced in 1960 by Scribner and others (22).* In the same year Quinton and others (20) developed an arteriovenous shunting device by means of prolonged external artery and vein cannulation. Although this technique was adopted in all centres for haemodialysis it presented several problems: clotting of the shunt, infection, haemorrhage, and partial occlusion leading to decreased flow, as well as embolic accidents during declotting procedures. Therefore a new method was sought, and in 1966 Brescia and others (1) introduced the internal arteriovenous fistula which facilitated the venepuncture technique for haemodialysis which had first been proposed by Cimino and Brescia (4) in 1962. However, this technique also has problems. The classic method of Brescia and others (1) for a surgically created arteriovenous fistula is a side-to-side anastomosis between the radial artery and the cephalic vein at the wrist level. This device necessitates a large patent cephalic or other neighbouring vein. However, in many cases such a vein cannot be found, particularly if shunts or fistulae have previously been performed in the same limb.

---

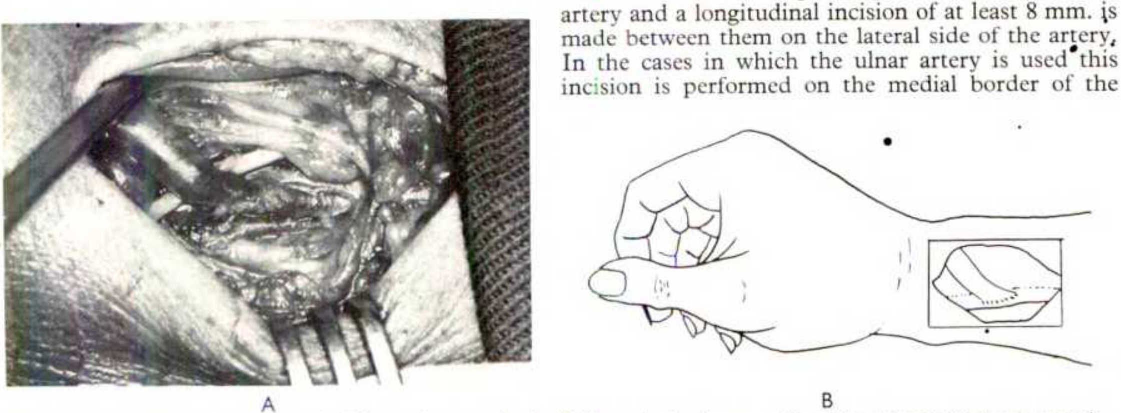

FIG. 1.—*Case* 7. A, Operative photograph of the arteriovenous fistula. B, Frame in the diagram outlines the part shown in the photograph.

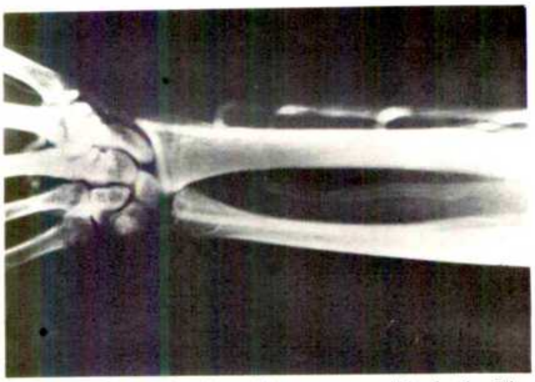

FIG. 2.—*Case* 7. Arteriographic appearance of the fistula. The apparent shortness of the venous arch in the film is due to the position in which the forearm was radiographed.

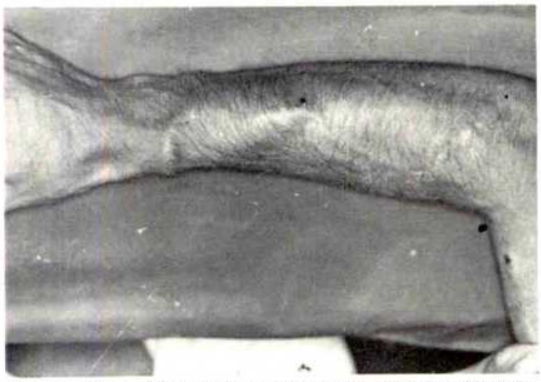

FIG. 3.—*Case* 3. Photograph of the forearm. Note the wide arch.

Several modifications have therefore been developed to overcome this problem (7, 13, 14, 16, 19, 21, 24). An alternative technique with the purpose of solving this and some other problems is presented here.

MATERIALS AND METHODS

An axillary block anaesthesia is used which seldom requires an additional local anaesthetic. One of the dorsal metacarpal veins is chosen, usually the one between the third and fifth metacarpal bones. A small transverse incision is performed on the dorsum of the wrist over the vein, which is then dissected distally to a point near the metacarpophalangeal joints. Occasionally it is necessary to perform a second incision over this point. The vein is transected as distally as possible and its digital end is ligated. The proximal part is pulled through the incision over the wrist. Another longitudinal incision is performed over the radial artery (or the ulnar artery in the cases in which the radial artery has been occluded by previous cannulations or fistulae). The artery is dissected for a distance of about 2 cm. A subcutaneous tunnel is prepared between the two skin incisions and the free part of the vein is arched through this tunnel to the artery. The aperture of the vein is enlarged to a width of 8–10 mm. either by a diagonal incision or, when the vein is very narrow, by longitudinal splitting and trimming of the corners. Two bulldog clamps are applied to the artery and a longitudinal incision of at least 8 mm. is made between them on the lateral side of the artery. In the cases in which the ulnar artery is used this incision is performed on the medial border of the vessel. The end of the vein is then anastomosed to the side of the artery with a 000000 running Tevdek suture so that the vein forms an acute angle with the distal part of the artery (*Fig.* 1). The clamps are removed and a pulse and thrill can immediately be detected over the vein which has become distended. The end-result is a wide arch, the blood flowing from the artery into the vein first in a distal direction, which then progressively becomes proximal. The arteriographic and external appearances of a limb in which a fistula has been performed are presented in *Figs.* 2 and 3.

RESULTS

During the period from November, 1970, to October, 1971, 14 arteriovenous fistulae using this technique were performed in the Department of General and Vascular Surgery, Rambam Government Hospital, on 14 patients on a chronic haemodialysis programme. In 1 additional patient a saphenous vein interposition graft was required as owing to several previous external arteriovenous shunts there were no remaining patent superficial veins at the wrists. The 14 cases are listed in *Table I*. Despite previous shunts and arteriovenous fistulae only in 2 cases was the radial artery obliterated and it was necessary to use the ulnar artery.

One of the patients died a few days after the fistula had been performed. The remaining 13 patients still have a patent fistula. Nine patients perform regular dialysis by means of their fistula in our haemodialysis unit. The remaining 4 patients have been transferred to other dialysis centres. One of these had regular dialysis until a successful kidney transplantation was performed, while the others are still on dialysis. The number of dialyses performed up to October, 1971, in the patients in our unit is given in *Table I*. The output values of the fistulae are also listed in *Table I*. The calibre of the arteries at the level of the anastomoses ranged between 1·5 and 3 mm. The veins were occasionally larger, but in some cases only a very narrow one could be found (less than 1 mm. in diameter in the collapsed state). Despite this a sufficiently large net of veins developed in the dorsum of the forearm and haemodialysis using the arteriovenous fistula could be performed in all the cases 2 days to 4 weeks after the creation of the fistula. No major oedema of the hand was noticed following the operation. No aneurysm of the venous limb occurred. As already stated, no immediate or late thrombosis of the fistulae or insufficient output prevented the regular use of the fistulae for chronic intermittent haemodialysis.

DISCUSSION

The superiority of internal arteriovenous fistulae over external ones has been well established (1, 3, 5, 8, 10, 15, 17, 18, 21, 25, 26). Not only has the internal fistula a much longer survival time but also complications such as haemorrhage and infection are practically nil. As already mentioned, the first internal arteriovenous fistulae were introduced by Brescia and others in 1966 (1). Today, this method is accepted in most centres (2, 3, 4, 5, 6, 8, 9, 10, 11, 17, 18, 23, 25, 26). However, an analysis of this technique reveals some pitfalls. A side-to-side anastomosis necessitates a neighbouring vein of good calibre. This cannot always be found, particularly when previous shunting operations have been performed at the same site. The blood-flow from the artery into the vein when the anastomosis is opened splits into two. One engages the distal part of the vein, and this reverse flow in the vein either leads to a certain degree of congestion of the hand or sometimes is stopped by valves and ceases completely. This is obvious in some of the arteriographs presented in the literature (10). However, in both cases the main flow through the anastomosis turns sharply in the proximal direction (*Fig.* 4). Such an acute angulation is of poor haemodynamic value, causing turbulence. This may be the reason for both aneurysmal changes in the venous limb and thrombosis of the fistula. While the occasional impossibility of creating a side-to-side arteriovenous fistula has given rise to modified techniques to overcome the problem, no attention has been given to the sharp angulation in the flow through the anastomosis.

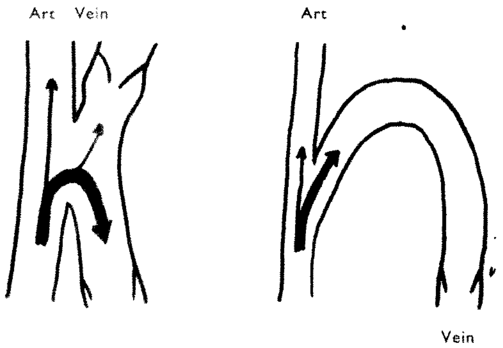

Fig. 4.—Diagrams of (A) side-to-side and (B) side-to-end arteriovenous fistulae, showing the sharp angulation of the blood-flow through the side-to-side anastomosis which is missing in the side-to-end type in which there is a wide arch.

Two main modifications to the Brescia technique have been published. The one advocated by Sperling and others (24) in 1967 and by Salomon and others (21) in 1968 is an end-to-end anastomosis between the radial artery and one of the veins in the forearm or wrist. This method allows the use of a distant vein but it necessitates the ligation of the radial artery. In cases in which one of the two arteries of the forearm is already obliterated or ligated by previous shunting operations the ligation of the second artery may put the blood-flow to the hand in jeopardy. Another method was proposed first by Florez-Izquierdo and others (7) in 1969 for children in whom the vessels in the wrist are very small and later was also advocated by Lazorthes and others (13), May and others (14), and Mozes and others (16).

They also used an interposition saphenous vein-graft. The first three groups of workers anastomosed the graft in the antecubital fossa, positioning the saphenous vein as a U loop in the volar part of the forearm, either side to side or end to end. Mozes and others (16) branched the saphenous vein to the artery at a right-angle in the wrist and brought it to the proximal vein in a Z shape. However, while Mozes and others (16) reported successful shunts in 2 patients, Lacombe and others (12), using the method of Lazorthes and others (13), claimed a 50 per cent failure rate, including thromboses and aneurysmal transformation of the graft, and recommended the discarding of this technique. Another major point in all saphenous graftings is the much longer time necessitated by the operation and the more complicated anaesthesia required (usually a general one) in poor-risk patients who are frequently in a bad general condition and prone to infection.

The technique proposed here is a simple one. It necessitates a minor anaesthetic procedure, it allows the use of a vein distant from the artery, a wide 8–10-mm. anastomosis is easily obtained, and the blood flowing through it causes little turbulence. The length of the operation is about 1 hour. Though the cause of the reported failures in the literature of the side-to-side technique has been attributed to either a small (less than 4 mm.) artery (25), a narrow vein (5, 6, 8, 10, 17, 26), or a narrow anastomosis (26) we have not been impressed by the first two of these factors as a possible cause for occlusion of the fistula. All the arteries in our cases were less than 4 mm. in diameter and we have also successfully used narrow veins. The width of the anastomosis is considered an important factor in the patency of the fistula. Though some authors consider a 3–5-mm. aperture sufficient (1, 8, 10, 17), many others advocate an 8-mm. one (5, 7, 15, 18, 19) and this is also our opinion. However, we consider an anastomosis of 15–35 mm. (26) as unnecessarily large. Compared with a 10–18 per cent failure rate in the side-to-side technique as reported by many authors (1, 5, 8, 10, 25, 26), and bearing in mind the problems which have been overcome by our technique, the result of our series, though a rather small one, is satisfactory.

a word of comfort after surgery

UBRETID®
distigmine bromide

maintains smooth muscle tone
prevents urinary retention or intestinal atony

UBRETID inhibits cholinesterase for a full 24 hours, giving prolonged improvement in smooth muscle tone. Thus, with minimum inconvenience to staff or patient, a normal pattern of micturition and defaecation can usually be re-established without the discomforts of catheters or enemata. Where indwelling catheters are unavoidable, **UBRETID** will maintain bladder tone, reduce residual urine volume and encourage normal bladder function when the catheter is withdrawn.
Full details of **UBRETID** ampoules and tablets are available upon request.

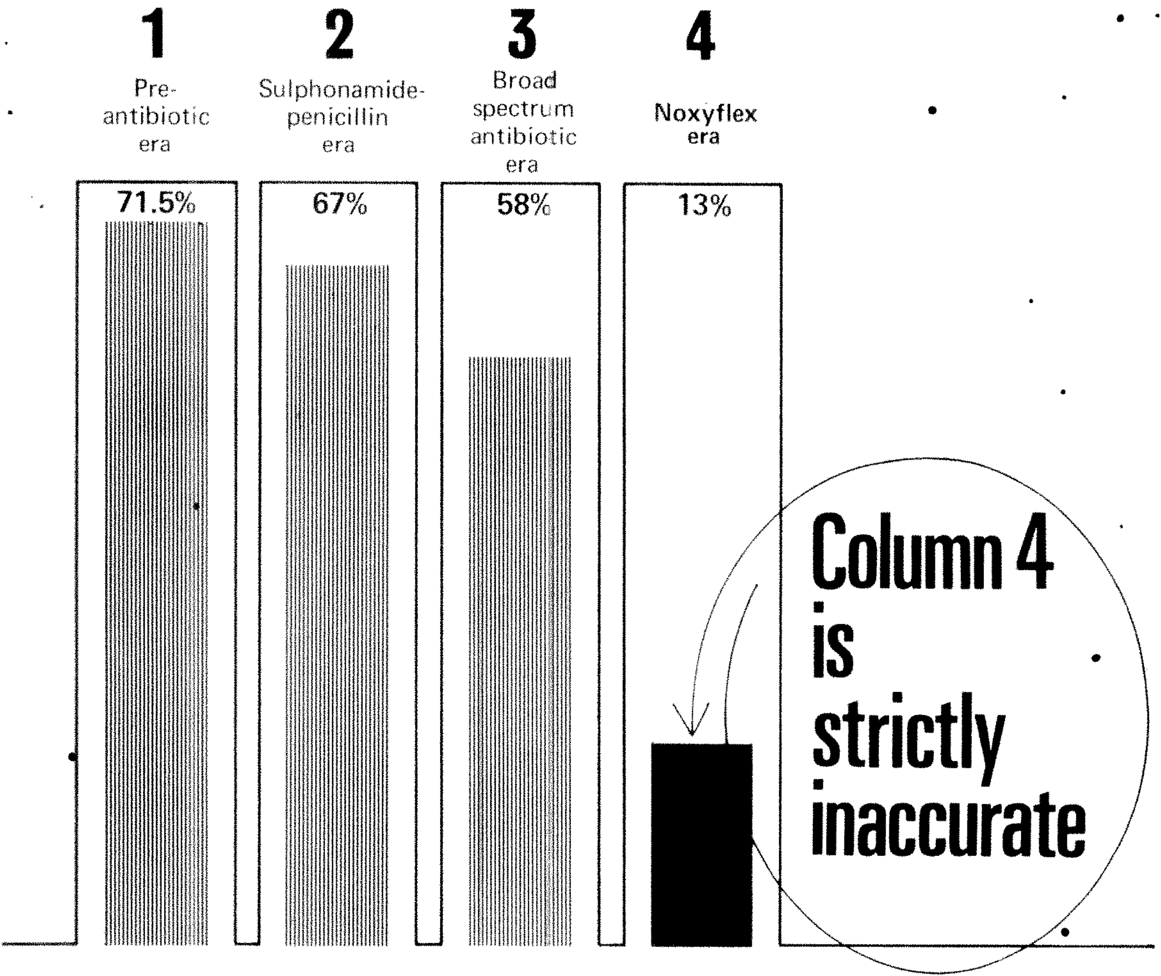
The graph below compares mortality rates due to faecal peritonitis, era by era.
It is not pedantically accurate because its sources differ. But the point is fairly made.



Column 4 is strictly inaccurate

Why inaccurate? Because column 4 refers to 23 cases of faecal peritonitis which were treated successfully with Noxyflex. But the *3 deaths which occurred were due to causes other than peritonitis - as post-mortem revealed. **The mortality rate due to peritonitis can therefore be regarded as zero.**

* The whole graph, and the causes of the deaths referred to are the subject of the new Noxyflex folder "Why three deaths?" You will receive at least one copy!

When bacterial contamination of the peritoneum is diagnosed or suspected: Noxyflex

ERYTHROCYTE AND PLASMA CIRCULATION TIMES IN HAEMORRHAGIC SHOCK

By D. F. L. WATKIN* and JENNIFER HUDSON

THE UNIVERSITY DEPARTMENT OF SURGERY, THE ROYAL INFIRMARY, AND THE REGIONAL MEDICAL PHYSICS DEPARTMENT, SHEFFIELD

SUMMARY

A method has been developed in which the simultaneous administration of ^{51}Cr-labelled red blood-cells and ^{125}I-labelled albumin in the dog has been used to compare the flow rates and transit times of erythrocytes and of plasma in three circulatory beds —the hindlimb, the kidney, and the small intestine. Blood-flow rates calculated from either isotope agreed well and were significantly greater than simultaneous direct measurements and electromagnetic flowmeter readings. This difference was due to incomplete recovery of the isotope from the venous cannula, recovery ranging from 23 to 96 per cent. When the isotope-flow results were corrected for these losses they did not differ significantly from direct measurements though they were still greater than the electromagnetic flowmeter readings.

The mean transit time for erythrocytes was, on average, 6–8 per cent shorter than that for plasma. There was no significant difference in this percentage for the three vascular beds studied or between a control period and haemorrhagic shock. Thus, in this shock preparation red-cell 'sludging' cannot have been extensive. The rationale for the use of low-molecular-weight dextran as a specific 'anti-sludging' agent in shock is, therefore, not supported.

CIRCULATORY shock is a state in which the circulation fails to meet the nutritional needs of the body at rest (Guyton and Crowell, 1964). The absolute reduction in blood-flow in shock may be accompanied by disruption of the orderly passage of erythrocytes through the capillaries, as seen by direct observation of the microcirculation using the techniques of Chambers and Zweifach (1944). Aggregation and slowing of the red cells, plasma skimming, and arteriovenous shunting have been observed in these circumstances (Gelin, 1961). The present paper is concerned with the first of these microcirculatory effects—the slowing of the flow of erythrocytes relative to plasma which is often described as 'sludging'. Low-molecular-weight dextran (L.M.W.D.) therapy is designed to correct this process (Bergentz, Gelin, Rudenstam, and Zederfeldt, 1961).

The evidence of *in vivo* microscopy is qualitative and is obtained in artificial situations, as with the rat's meso-appendix spread on a microscope stage. To provide a quantitative measure of any relative slowing of the red cells their transit times from artery to vein have been compared with those for plasma. In health the circulation time for erythrocytes is 10–15 per cent shorter than that for plasma (Rowlands, Groom, and Thomas, 1963), the difference being attributed to axial streaming of cells in the smaller blood-vessels. If the changes seen on microscopy are occurring on a physiologically important scale, then in shock the mean transit time should be longer for erythrocytes than for plasma.

METHODS

The measurements were made in 14 anaesthetized mongrel dogs weighing from 15 to 32 kg. (mean, 21·6 kg.). Transit times for red cells and plasma were compared before and after the production of haemorrhagic shock. The experimental method was established in the hindlimb and subsequently was applied to the renal and intestinal vascular beds in separate series of experiments.

For each comparison a bolus containing ^{51}Cr-labelled erythrocytes and ^{125}I-labelled albumin was injected via a small catheter placed in the artery supplying the organ under investigation. The radioactivity in its venous effluent was monitored by a scintillation counter connected to twin-channel ratemeters and recorders. From the indicator-dilution curves mean transit times and flow rates have been calculated. These flow rates were compared with simultaneous measurements by an electromagnetic flowmeter and also, in some experiments, with direct measurements. In 8 experiments the venous effluent was collected and its radioactivity was measured to assess the proportion of the injected bolus returning via the monitor.

Indicators.—The radioactive labels for erythrocytes and plasma were selected for stability and for their suitability for simultaneous monitoring by an external counter. ^{51}Cr has a γ energy of 323 keV. and is readily distinguishable from ^{125}I which has a 35-keV. γ emission and a 27-keV. X emission. A sample of the dog's own red blood-cells (R.B.C.) was labelled with ^{51}Cr by the method of Gray and Sterling (1950). ^{125}I-tagged human serum-albumin (H.S.A.) was obtained commercially (Radiochemical Centre, Amersham). The radioactivity of an accurately diluted 'standard' of each stock preparation was measured using the same counter as was employed for the venous stream. The two indicator preparations were combined in a 2-ml. plastic syringe immediately before injection, the quantities being measured by weighing. Approximately 50 μc. of ^{51}Cr R.B.C.s and 4 μc. of ^{125}I H.S.A. were used for each injection.

Instrumentation.—The radioactivity of the venous blood was monitored as it passed through a thin-walled polythene tube of 7 mm. internal diameter in front of a 2·5-cm.-diameter, 2·5-cm.-thick, sodium-iodide crystal and a photomultiplier. This scintillation counter was connected to twin-channel amplifiers and pulse-height analysers. The ^{51}Cr channel counted only pulses of over 85 keV., while the ^{125}I channel was set to accept those in the range 22–36 keV. The system gave counting efficiencies of 0·65 per cent for ^{51}Cr and 9·7 per cent for ^{125}I. ^{51}Cr was also recorded on the ^{125}I channel with an efficiency of 0·025 per cent. The output from the pulse-height analysers was fed into ratemeters connected to a twin-channel pen-recorder.

---

* Present address: Leicester Royal Infirmary.

Venous blood-flow was also measured by a cannulated electromagnetic flowmeter recording on a Grass polygraph recorder. At the end of each experiment this instrument was calibrated against a pump.

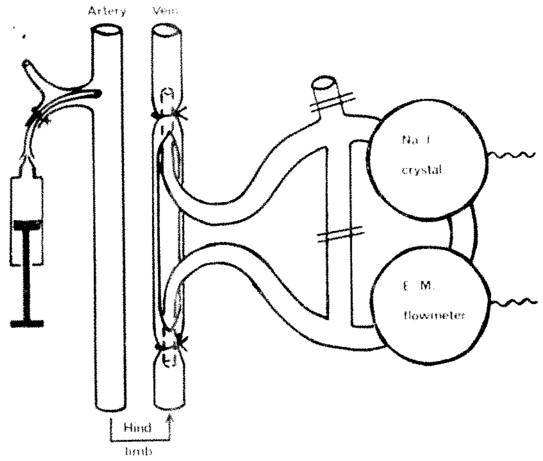

FIG. 1.—Cannulations and venous circuit for the hindlimb experiments.

The radioactivity of samples of the venous blood collected after passage through the monitor was measured in a well counter cross-calibrated with the original isotope 'standards'.

The Animal Preparation.—Anaesthesia was induced with intravenous thiopentone and maintained by intermittent intravenous pentobarbitone. The dog was ventilated with air at 170 ml. per kg. per minute via a cuffed endotracheal tube. A long catheter passed via the right femoral vein into the right side of the heart was used to obtain central venous samples for haematocrit estimations and for the administration of drugs. The right femoral artery was cannulated for continuous recording of the blood-pressure and to permit bleeding into a graduated bottle. A fine plastic catheter (1·6 mm. external diameter) was placed with its tip in the main artery supplying the organ to be studied. The injections of the isotopes were made by needle puncture through a rubber diaphragm covering the hilt. For the femoral and superior mesenteric arteries the catheter was introduced through a small branch. When investigating the renal circulation it was passed into the right renal artery, across the aorta, and manipulated into the left renal artery.

Cannulae placed in the femoral, renal, or portal veins were used to divert the entire venous stream through the circuit, which is shown connected for the hindlimb experiments in *Fig.* 1. The blood was returned to the dog via a proximal cannula in the femoral or portal vein; in the renal experiments the circuit led to a femoral cannula. The circuit consisted of the electromagnetic flowmeter, the scintillation counter, and a side-arm through which the blood could be diverted into a measuring cylinder. A cross-arm controlled with a haemostat served to zero the flowmeter. Heparin (500 U. per kg.) was administered to prevent clotting in the circuit in the limb experiments, but proved unnecessary at the higher flow rates obtained in the renal and intestinal studies.

Experimental Groups.—The hindlimb was studied in 6 dogs, the kidney in 4, and the intestinal circulation in 4. In 4 of the hindlimb experiments the venous blood was collected during the recording of each pair of isotope dilution curves. The larger volumes rapidly removed in this way in the renal and intestinal studies were not well tolerated and therefore 'collections' were restricted to the final 'control' and 'shock' readings in 2 experiments from each of these groups.

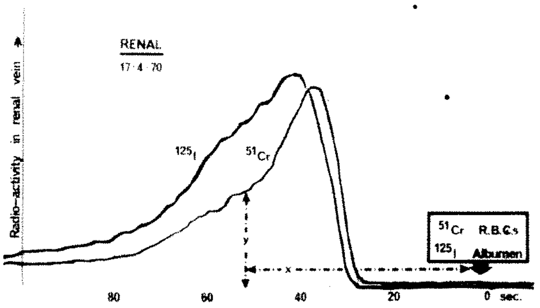

FIG. 2.—Method for analysis of indicator-dilution curves.

Experimental Procedure.—After the cannulations had been carried out the procedure was as follows:—

1. *Control Period* (0–30 minutes).—Three combined injections of ^{125}I H.S.A. and ^{51}Cr R.B.C.s were made at 15-minute intervals.
2. *Controlled Hypotension* (30–75 minutes).—The dog was bled to a systolic blood-pressure of 30–40 mm. Hg for 45 minutes. If the volume bled was less than 25 ml. per kg. in the limb experiments or less than 20 ml. per kg. in the other two groups the animal was excluded from the series.
3. *Shock Period* (75–105 minutes).—Three further dual isotope injections were made at 15-minute intervals.

Analysis of the Indicator-dilution Curves.—A typical pair of curves is shown in *Fig.* 2. Before each injection the recording was adjusted to zero in order to eliminate the background radioactivity due to equilibration of the previous injections. Two calculations were made from each curve: the blood-flow and the mean transit time of the indicator. Each curve was analysed by measuring its height (y) at 2-second intervals. From the sum of these heights was derived the area under the curve for use in the indicator-dilution blood-flow calculation (Powers and Sevelius, 1965). Each value of y was then multiplied by the time which had elapsed since injection (x). The mean transit time (M.T.T.) for an indicator is then given by the equation:—

$$\text{M.T.T.} = \sum xy \Big/ \sum y.$$

As no recirculation point could be identified on the curves they were counted to three times the transit time of the peak. Using this convention, the last point counted was always close to the level of the final equilibrium.

RESULTS

The volume bled averaged 31·9 ml. per kg. in the hindlimb experiments, 25·2 ml. per kg. in the renal experiments, and 25·6 ml. per kg. in the intestinal studies. The mean haematocrit following haemorrhage was 3·9 per cent lower than in the control period, indicating that relatively little haemodilution was occurring during the time span of the experiments. The severe degree of shock produced is demonstrated by the deaths of 3 other dogs before completion of the bleeding phase and of 2 more shortly before the final isotope injection was due.

Flow Measurement.—The flow rates calculated from the ^{125}I H.S.A. and ^{51}Cr R.B.C. dilution curves are compared in *Table I*. The mean values agreed well in both the control and the shock periods in each vascular bed. When the ^{125}I H.S.A. results are expressed as a percentage of the ^{51}Cr R.B.C. results the mean value ranges from 98·8 to 104·4 per cent with a standard deviation of 11·1 per cent or less, showing that the individual pairs of values were in close agreement. However, the flow rates obtained by the isotope method (expressed, for simplicity, as the mean of the ^{125}I H.S.A. and ^{51}Cr R.B.C. figures) were significantly greater than the electromagnetic flowmeter readings (*Table II*). The mean ratio between these two measures of blood-flow varied with the organ being studied, ranging from approximately 3 : 1 in the hindlimb to 4 : 3 in the small intestine. The ratio also tended to be higher during the shock period. The discrepancy between the isotope-flow results and the electromagnetic flowmeter readings varied considerably between experiments, as indicated by the large standard deviation of the ratio seen in *Table II*. A possible explanation for the differences between these two methods of measurement of blood-flow is considered later.

Kidney	4	10·3 ± 2·4	7·2 ± 2·2	150 ± 46	2·0 ± 0·7	1·1 ± 0·6	269 ± 208
Small intestine	4	14·7 ± 4·7	11·5 ± 2·3	125 ± 24	4·4 ± 0·7	3·1 ± 0·7	137 ± 30

* Three readings in each period in each dog.

† For each comparison of isotope and electromagnetic flowmeter results $P < 0·01$.

Isotope Recoveries.—The mean percentages of the injected isotopes recovered in the 8 'collection' experiments are shown in *Table III*. There was no significant difference between the recoveries of the two isotopes in either the control period or in shock. The percentage recovery of ^{125}I was significantly greater during the control period than in shock ($P < 0·02$), but the corresponding difference for ^{51}Cr recovery just failed to reach significance at the 5 per cent level. The large standard deviations of the percentage recoveries reflect the wide range of individual values which are given in detail in *Table IV*. Presumably the incomplete recovery of the isotopes was due to some of the injected material spilling over into the aorta or returning by other venous channels.

Table III.—PERCENTAGE RECOVERY OF INJECTED ISOTOPES IN 8 EXPERIMENTS

ISOTOPE	CONTROL PERIOD	SHOCK PERIOD	PAIRED t-TEST
^{125}I	72 ± 23	57 ± 29	$P < 0·02$
^{51}Cr	71 ± 22	59 ± 27	$0·05 < P < 0·06$

Corrected Indicator-dilution Flow Rates.—The indicator-dilution blood-flow calculation,

$$F = \alpha\ (I/A)$$

(where F = flow, I = radioactivity injected, A = area under the dilution curve, and α is a geometric constant), assumes that all the injected material reaches the monitor. Thus, in these experiments, the radioactivity injected must be multipled by the percentage recovery to give a 'corrected' flow rate. *Table IV* shows the uncorrected and corrected isotope-flow results and compares them with direct flow measurement and with the electromagnetic flowmeter readings.

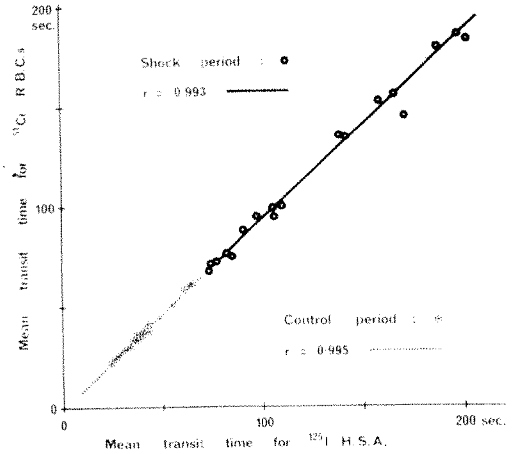

Fig. 3.—Mean transit times for erythrocytes and plasma in the hindlimb.

Table IV.—UNCORRECTED AND CORRECTED ISOTOPE-FLOW RESULTS COMPARED WITH DIRECT MEASUREMENT AND THE ELECTROMAGNETIC FLOWMETER RESULTS* (Flow expressed as ml. per kg. per minute)

VASCULAR BED STUDIED	DOG NO.†	MEAN ISOTOPE FLOW (UNCORRECTED)	MEAN PERCENTAGE ISOTOPE RECOVERY	ISOTOPE FLOW CORRECTED FOR PERCENTAGE RECOVERY	DIRECT FLOW	ELECTROMAGNETIC FLOWMETER
Control period						
Hindlimb	3	7·6	33	2·5	2·9	2·8
	4	2·9	60	1·7	1·8	1·3
	5	11·9	53	6·4	4·5	2·6

	12	10·1	95	9·6	9·2	9·2
Shock period						
Hindlimb	3	2·2	23	0·5	0·5	0·7
	4	1·7	36	0·6	0·7	0·4
	5	2·3	35	0·8	1·0	0·3
	6	1·9	70	1·3	1·3	0·9
Kidney	7	2·2	96	2·1	—	0·7
	8	1·8	72	1·3	1·0	0·6
Small intestine	11	4·2	40	1·7	1·4	2·4
	12	4·5	91	4·1	4·3	3·6

* For hindlimb experiments each line is the mean of three readings but for renal and intestinal studies it represents a single reading.

† Statistical analysis: uncorrected isotope flow was significantly greater than direct measurement or the electromagnetic flowmeter in each period ($P < 0{\cdot}02$). Corrected isotope flow was not significantly different from direct measurement. Corrected isotope flow was significantly greater than the electromagnetic flowmeter result in shock but not in the control period.

The uncorrected isotope-flow result in these 8 experiments was a mean of 165 per cent of the direct flow in the control period and of 232 per cent in shock. The corresponding figures for isotope flow and the electromagnetic flowmeter were 224 per cent and 324 per cent. Each of these differences is statistically significant ($P < 0{\cdot}02$).

After correction for percentage recovery, the isotope results were a mean of 108 per cent of direct-flow measurement in the control period and of 103 per cent in shock, neither difference being statistically significant. The corrected isotope-flow results were still respectively 147 per cent and 167 per cent of the electromagnetic flowmeter readings in the control and shock periods, the former difference being significant at the 5 per cent level. Thus, the incomplete recovery of the isotopes provides a satisfactory explanation for the differences between isotope and direct-flow measurements, and partially explains the discrepancy between the isotope method and the electromagnetic flowmeter.

Mean Transit Time.—The mean transit time for both plasma and erythrocytes varied with the organ studied. During the control period the average for the two isotopes ranged from 14·1 (± 2·2) seconds for the renal circulation to 31·4 (± 5·0) seconds for the intestine, and 40·5 (± 11·8) seconds for the hindlimb. In shock the mean values were 79·7 (± 43·7) seconds for the small intestine, 92·7 (± 42·8) seconds for the kidney, and 121·8 (± 42·0) seconds for the hindlimb.

In every instance the mean transit time was shorter for erythrocytes than for plasma. The excellent correlation between the paired values in the hindlimb is shown in *Fig.* 3, the correlation coefficient being 0·997 for the control period and 0·993 in shock. The regression lines for the control and shock periods are not significantly different. The results for the renal and intestinal circulations showed a very similar pattern.

Comparisons between the relative transit times for erythrocytes and plasma in the three vascular beds and in the control and shock periods have been made by expressing the mean transit time for erythrocytes as a percentage of the concurrent result for plasma. The individual values ranged from 84·1 per cent to 98·9 per cent. The mean values for each vascular bed in the control and shock periods are given in *Table V*. They range from 92·4 (± 3·8) per cent in the renal circulation in the shock period to 94·0 (± 3·5) per cent in the small intestine, also in shock. Student's *t*-test showed no significant difference between any two organs, or between the control period and the shock period in any of the vascular beds studied ($P > 0\cdot 2$ in every case).

DISCUSSION

A dual-label isotope technique such as this does not appear to have been applied previously to a comparison of erythrocyte and plasma circulation times in shock. The method therefore requires careful appraisal.

Blood-flow.—The good correlation observed between the whole-blood flow rates calculated from the dilution curves for each isotope (*Table I*) indicates that the measurements of radioactivity in both the control and the shock phase were of satisfactory accuracy. Conventional reproducibility studies were impracticable because equilibration of the injected isotopes throughout the animal is required before the next reading; during this 15-minute period the flow rates (as indicated by the electromagnetic flowmeter) often changed. An explanation is required for the difference (up to threefold) between the blood-flow as measured by the isotope-dilution technique either directly or by the electromagnetic flowmeter. Strictly, the indicator-dilution method of blood-flow measurement gives the flow in the artery into which the injection is made and assumes that the whole bolus passes peripherally in that artery and ultimately reaches the venous monitor (Powers and Sevelius, 1965). Our experimental preparations may fail to meet these ideals in two respects: some of the injected material may spill over into arteries upstream of the catheter tip and so perfuse other vascular beds and, in the limb, part of the venous return may by-pass the cannulation site. Even though the kidney appears to have an ideal 'end artery' for these studies, a rapid injection could reflux into the aorta. Experiments have confirmed that soon after injection via the renal or superior mesenteric arterial catheters a brief peak of radioactivity can be detected over the femoral artery. The vascular anatomy of the hindlimb is also compatible with the second explanation, for a large profunda femoris vein joins the common femoral vein just above the level of cannulation and could account for the lower percentage recoveries in this group of experiments. The variation in isotope recovery rates between individual experiments on the same organ may be attributed to differences in the siting of the catheter tip, or in the volume of the bolus (Hobbs, Agrifolio, and Edwards, 1962), or in the relative sizes of main and collateral veins. The lower recoveries in shock may be due to greater arterial overspill occurring at lower flow rates. These suggested explanations for the differences between the uncorrected isotope blood-flow rates and the electromagnetic flowmeter readings are supported by the improved relationships obtained after correction of the former for the percentage recovery of the isotopes (*Table IV*). The residual 25 per cent difference between the corrected isotope results and the electromagnetic flowmeter measurements is similar to the 19 per cent excess of the isotope-dilution flow results over the readings of a mechanical flowmeter reported by Hobbs and others (1962). Both differences are unexplained.

The values obtained for regional blood-flow vary widely between authors. Hobbs and others (1962), in a review of the literature concerning femoral arterial flow in the dog, found results ranging from 1·4 to 41·0 ml. per minute per kg. body-weight. In this context our results, using a cannulated electromagnetic flowmeter, are consistent with recent reports of measurements by a 'wrap-around' instrument (*Table VI*).

The calculation of mean transit times from the indicator-dilution curves, fortunately, is not dependent upon any assumptions concerning isotope-recovery rates. The finding in the control period of erythrocyte transit times 6–8 per cent shorter than those for plasma is in accordance with previous reports. There were no significant differences between the three vascular beds studied (*Table V*). Rowlands and others (1963), using the anaesthetized cat, found that red-cell transit from the femoral artery to the femoral artery was 14 per cent shorter than that for plasma. This effect was considered to be due to axial streaming of erythrocytes in the smaller blood-vessels. A similar mean difference of 14·5 per cent had been found in the renal circulation in dogs by Lilienfield, Rose, and Porfido (1957), though they attributed it to preferential arteriovenous shunting of erythrocytes. In man Larsen and Lassen (1964) reported a mean 12 per cent lead for red cells over plasma between the carotid artery and the jugular bulb.

The more rapid transit time for erythrocytes must, in a steady state, be accompanied by a lower haematocrit in the microvasculature than in large vessels. Williams (1965) has demonstrated such a relationship in dogs. The whole-body haematocrit was measured by a dual-label equilibration method and erythrocyte and plasma transit times were compared using the same indicators. The shorter the transit time of the red cells relative to the plasma, the lower was the ratio of the whole-body haematocrit to the venous haematocrit. Thus, the ratio of erythrocyte to plasma transit times provides an indirect measure of the haematocrit of the blood flowing through the microcirculation.

Haemorrhagic Shock.—The normal relationship between erythrocyte and plasma transit times was not significantly altered in this haemorrhagic shock preparation (*Fig.* 3; *Table V*). There was not a single reading in which the red cells were slower than the plasma. These results do not appear to be compatible with a haemodynamically significant degree of slowing of erythrocytes relative to plasma or with any increase in the microvascular haematocrit. They imply that the normal axial streaming of red cells is maintained.

These findings are in conflict with the evidence of *in vivo* microscopy. Chambers, Zweifach, and Lowenstein (1943) described slowing of erythrocytes relative to plasma in the whole rat following trauma inflicted in a rotating drum, and Knisely, Eliot, and Bloch (1945) noted this change in the vicinity of a localized injury. Subsequently similar observations were made in haemorrhagic shock (Zweifach, Chambers, Lee, and Hyman, 1948). A good correlation between the severity of the microscopic changes in the omentum and the percentage of the original blood-volume shed (Schumer and Durrani, 1963) suggests that the changes are closely related to the severity of shock. There are, however, three dissenting reports: Page and Abell (1943) did not see pooling or slowing of red cells in cats in tourniquet shock, while Bellman, Lambert, and Fine (1962) saw sludging in rabbits in haemorrhagic shock only in the vicinity of local trauma; in dogs in haemorrhagic shock Stallworthy, Ramirez, Barrington, and Bradham (1969) found no slowing or margination of individual R.B.C.s, though they did note the formation of masses of erythrocytes when flow temporarily ceased in a vessel. *In vivo* microscopy has two apparent limitations: although erythrocyte movement is obvious the plasma flow rate can only be inferred from the movement of platelets; also the appearances may be dependent upon local damage resulting from placement upon the microscope stage or insertion of a quartz rod into a solid viscus for illumination.

The discrepancy between the quantitative findings in our experiments and the changes reported on microscopy might be due to an insufficiently severe degree of shock in the present study or to some misinterpretation of the microscopic appearances. The volumes bled and the resulting reductions in blood-flow were similar to those reported by others (*Table VI*). Unfortunately, the descriptions of microcirculatory changes in haemorrhagic shock do not include measurements of regional blood-flow, but Schumer and Durrani (1963) and Matsumoto, Hardaway, and McClain (1967) do state that the 'sludging' of erythrocytes occurred as haemorrhage approached 50 per cent of the initial blood-volume. We have no data for blood-volume, but taking the initial value as 9·25 per cent of body-weight (Sjöstrand, 1962) the volumes bled in the present series would range from 26 to 42 per cent of the total. The deaths of 5 dogs before completion of the experiments likewise argue that our animals were truly shocked. Nevertheless, a more prolonged shock procedure or induction by methods other than haemorrhage might yield different results.

Hardaway and Drake (1963) have offered an alternative interpretation of the microvascular changes in shock. They consider that as shock proceeds an increasing proportion of the small blood-vessels becomes occluded by thrombosis. The present dynamic studies would be unlikely to register immobilization of erythrocytes by this process. The heparin given in the experiments on the hindlimb might prevent such microthrombosis, but as heparin was not used in the renal and intestinal studies it cannot be responsible for our inability to detect 'sludging' of red cells.

CONCLUSIONS

The discrepancy between the lack of slowing of erythrocytes relative to plasma in our quantitative studies and the 'sludging' seen on microscopy seems likely to be the result of a misinterpretation of the latter appearances. These may represent a combination of an effect of local trauma and the development of microvascular thromboses. There is at present no quantitative haemodynamic evidence to provide a rationale for the choice of an 'anti-sludging' agent, such as low-molecular-weight dextran, for intravenous infusion in haemorrhagic shock.

THORACIC ENTERIC CYSTS AND DIVERTICULAE

BY SAEED AHMED, AMBROSE JOLLEYS,* AND JOHN F. DARK
ROYAL MANCHESTER CHILDREN'S HOSPITAL, PENDLEBURY

SUMMARY

Six cases of thoracic enteric cysts and diverticulae are described to illustrate a manifestation of the split notochord syndrome. The varied clinical, radiological, and operative picture in these cases is emphasized, the common triad being respiratory symptoms, a posterior mediastinal mass, and a vertebral anomaly. The symptoms may, however, be entirely gastro-intestinal in the form of abdominal enlargement or gastro-intestinal haemorrhage. Because of the diversity of presentation these patients may come under the domain of the paediatric surgeon, the thoracic surgeon, or the neurosurgeon, and occasionally a combined team approach may be required to obtain satisfactory results in surgical treatment, which is mandatory.

ALIMENTARY tract duplications, to use the term in its broadest sense, may occur anywhere from the mouth to the anal canal. The duplications have a wall in which normal bowel structure is reproduced and a mucosal lining in which one or more types of epithelium are represented. From an aetiological point of view the duplications may be divided into two groups:—

1. Those that result from a localized fault in development and include most intra-abdominal duplications, which are not discussed further in this paper.
2. Those associated with vertebral anomalies and include thoracic enteric cysts and duplications, which, according to the terminology proposed by Bentley and Smith (1960), should be called 'prevertebral enteric cysts' and 'thoracic enteric diverticulae'.

Vertebral anomalies are also seen in association with duplications of the colon and the anal canal (Soper, 1968; Smith, 1969), although not as frequently as in thoracic duplications. Occasionally a thoracic duplication may be seen without a demonstrable vertebral anomaly.

Apart from enteric malformations, developmental anomalies of the skin and the central nervous system are often seen in association with vertebral anomalies. These may be included collectively under the term the 'split notochord syndrome' (Bentley and Smith, 1960). The purpose of this paper is to review the clinical manifestations of this syndrome as applied to thoracic enteric cysts and diverticulae which are illustrated by 6 cases admitted to the Manchester Children's Hospitals during the years 1960 up to 1971. All the cases occurred in male children, all of whom survived.

CASE REPORTS

Case 1.—D. W. has previously been reported by Goldberg and Johnson (1963). He presented at the age of 6 days having had breathlessness and cyanosis since birth. A chest radiograph showed an air-filled cyst in the right lower chest and a spinal anomaly, which consisted of hemivertebrae of the whole cervical and upper dorsal spine.

Barium-meal and follow-through examination showed a normal stomach and malrotation of the midgut. In addition barium was seen to enter a blind loop of jejunum and pass upwards through the diaphragm into the right pleural cavity, where it filled the previously noted air-filled cyst. Through separate abdominal and thoracic incisions, a massive thoracic enteric diverticulum was removed, along with a segment of normal jejunum with which it communicated. The child made an excellent postoperative recovery and is now 10 years old with no disability and no positive neurological signs although a chest radiograph shows a complex anomaly of the cervico-dorsal spine (*Fig.* 1).

The surgical specimen consisted of small intestinal structures only. It was 33 cm. long (9·5 cm. subdiaphragmatic and 23·5 cm. supradiaphragmatic) and joined the resected jejunum obliquely end to side.

Case 2.—I. W. was first admitted to Manchester Children's Hospital at the age of 2 years. At birth he had had severe respiratory depression, which was considered to be due to an intracranial haemorrhage, from which he had recovered satisfactorily. This had been followed by several episodes of respiratory infection and his mother also thought that on one occasion his sputum had been blood-stained.

---

* Correspondence to Mr. A. Jolleys, Royal Manchester Children's Hospital, Pendlesbury, Manchester M27 1HA.

At birth he had also been noticed to have a large abdomen which had become bigger (*Fig.* 2). A barium enema had shown no evidence of Hirschsprung's disease. Later he had had abdominal pain and vomiting and he had brought up blood and mucus.

A barium-meal examination showed a normal oesophagus and stomach with no evidence of gastro-oesophageal reflux. A follow-through film showed no change in the bowels except for failure of descent of the caecum. He had some occult blood in the stools and

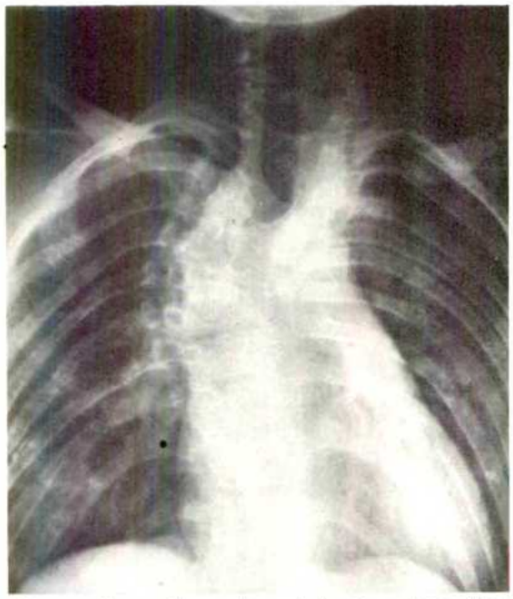

Fig. 1.—*Case* 1. Chest radiograph showing scoliosis. Hemivertebrae in the cervical and dorsal spine up to D.V. 7, and diastematomyelia were noted on tomograms.

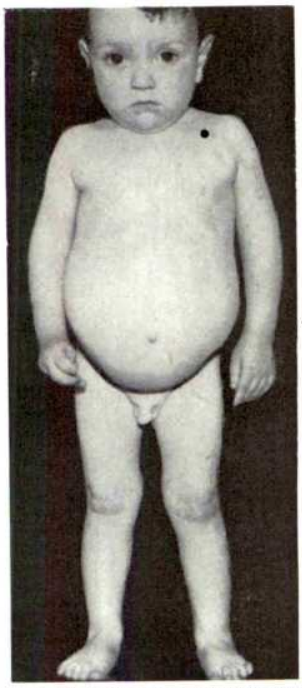

Fig. 2.—*Case* 2. I. W., aged 2 years, showing abdominal enlargement in an otherwise well-nourished child.

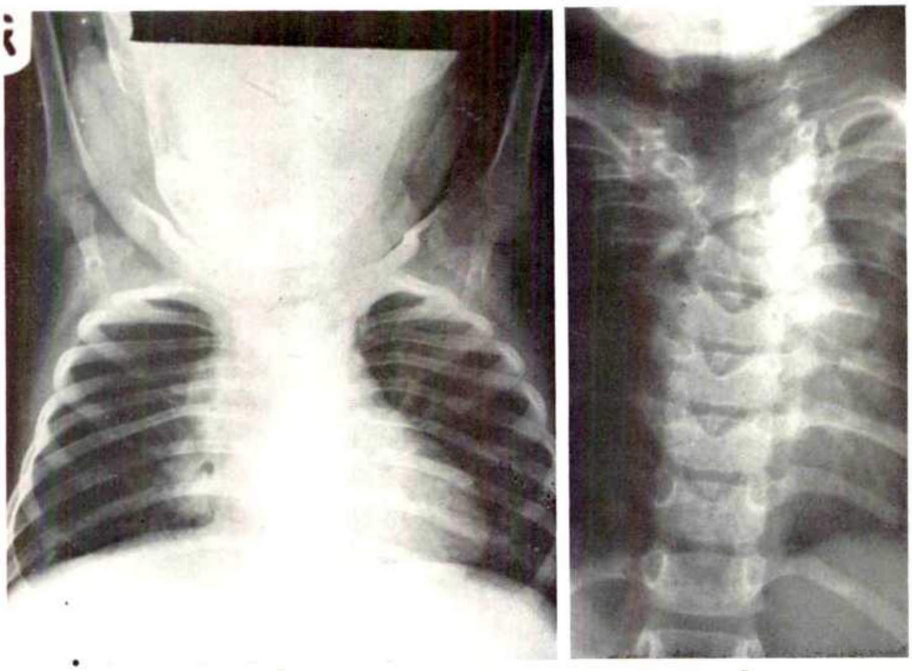

A

B

Fig. 3.—*Case* 2. A, Preoperative chest radiograph showing a right hilar shadow. An anomaly of the spine had also been observed preoperatively but a hemivertebra (D.V. 4) is more clearly seen in B, which is a postoperative film.

an iron-deficiency anaemia. Liver-function tests and absorption studies were normal.

Some months later a chest radiograph showed a hilar shadow on the right and an anomaly of the upper dorsal spine (*Fig.* 3). The significance of this was not appreciated at first. Investigation for tuberculosis was negative. After a frank haemoptysis, a tomogram and bronchoscopy were performed.

The radiographs showed compression of the right main bronchus by a mass and enlargement of the perihilar

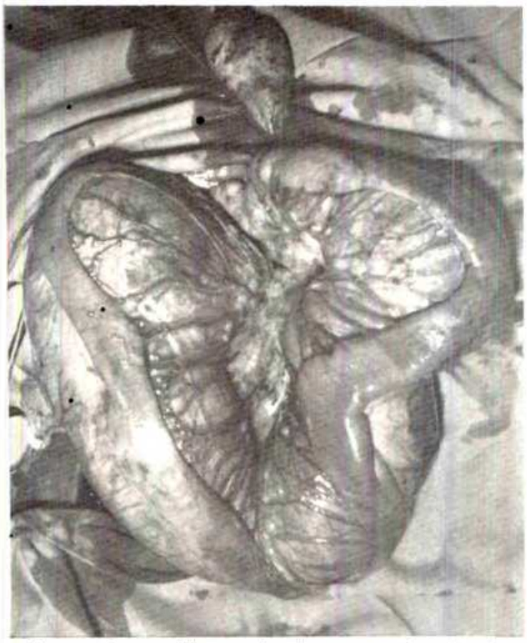

FIG. 4.—*Case* 2. Photograph taken at operation showing a massive jejunal duplication lying in the mesentery with the normal bowel stretched over it. The upper blind end of the duplication is seen at the top of the picture.

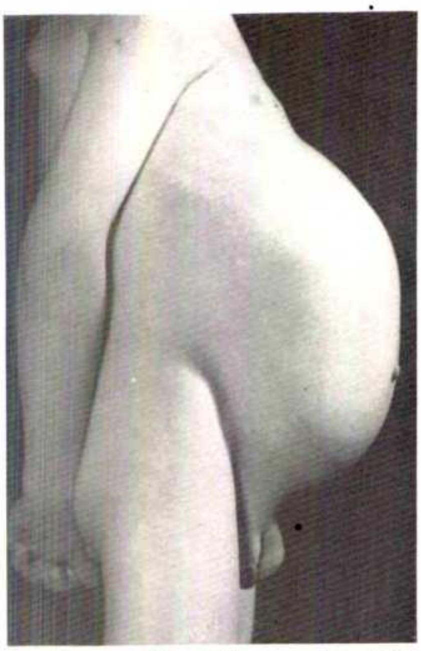

FIG. 5.—*Case* 4. H. B., aged 5 years, with a very large protuberant abdomen.

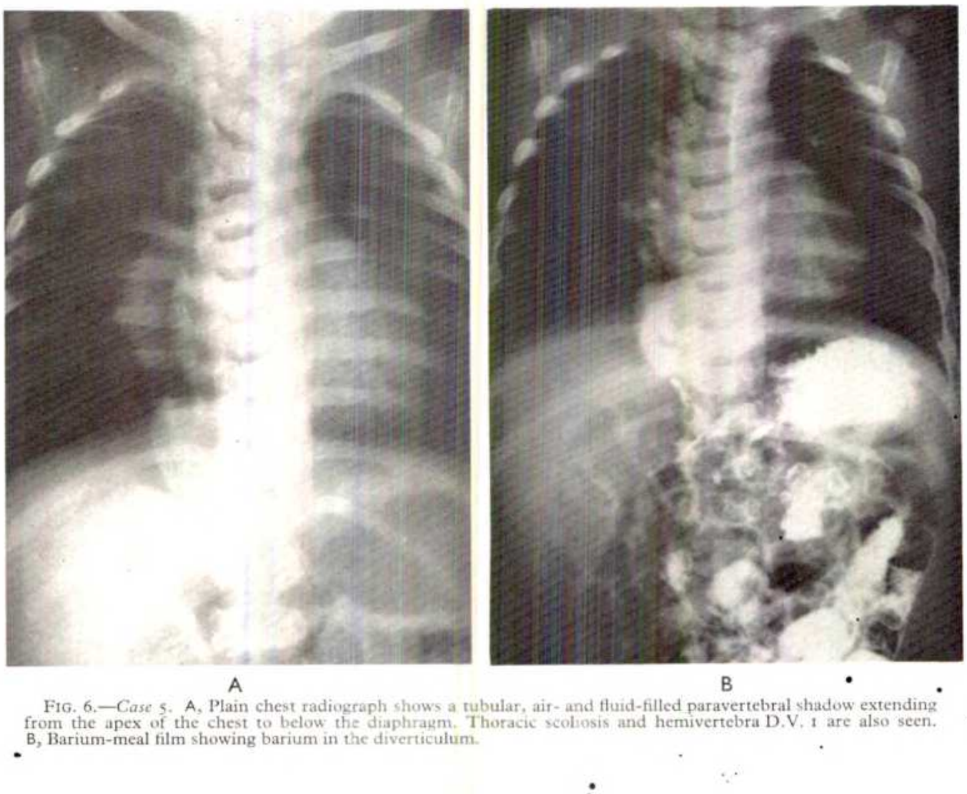

FIG. 6.—*Case* 5. A, Plain chest radiograph shows a tubular, air- and fluid-filled paravertebral shadow extending from the apex of the chest to below the diaphragm. Thoracic scoliosis and hemivertebra D.V. 1 are also seen. B, Barium-meal film showing barium in the diverticulum.

lymph-glands. Bronchoscopy (J. F. D.) confirmed that the right main bronchus was occluded by an ulcerated mass. Biopsy showed some gastric tissue with peptic ulceration. This finding along with the vertebral anomaly eventually indicated the diagnosis of thoracic enteric cyst.

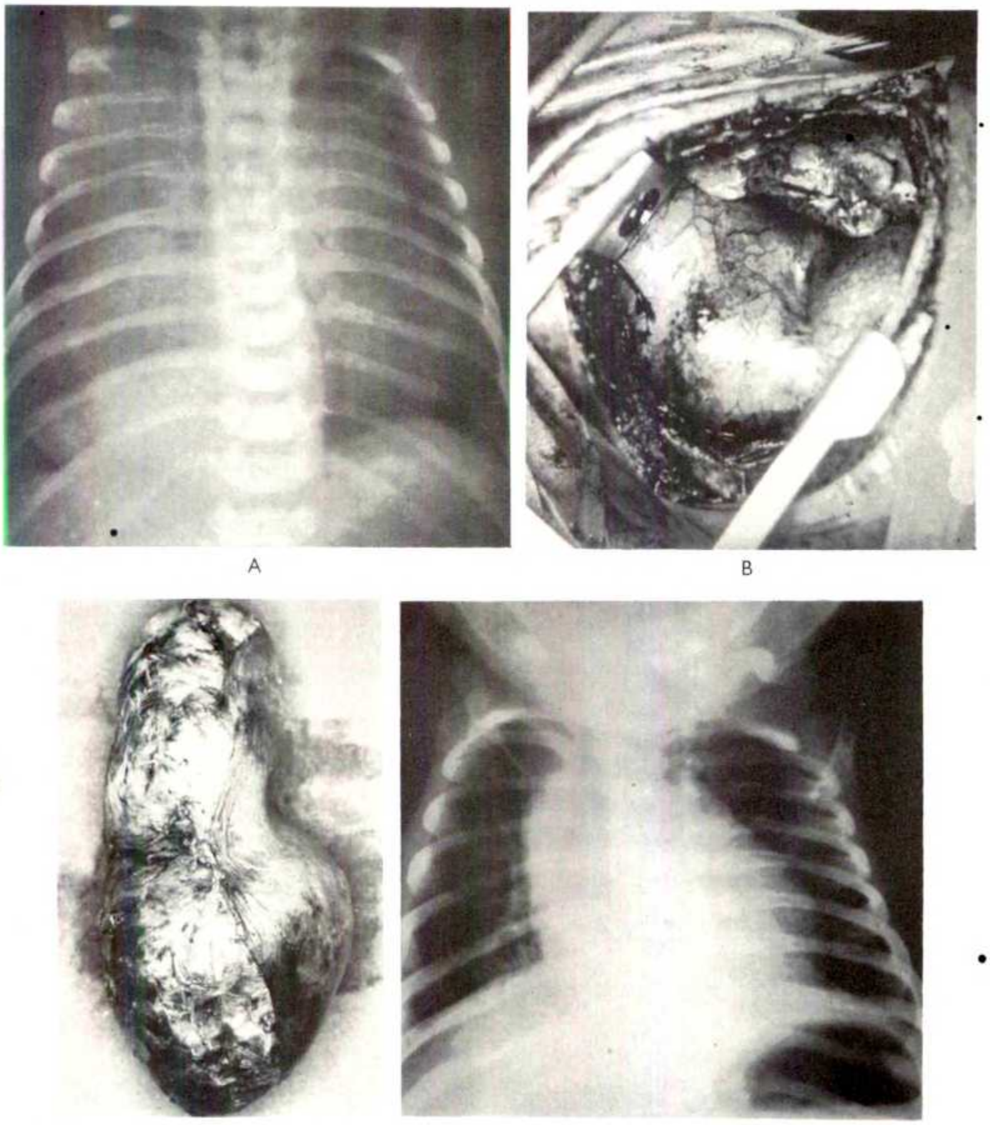

FIG. 7.—*Case* 6. A, Preoperative chest radiograph showing a large opaque mass occupying the right side of the chest. B, Operative photograph showing the cyst bulging forward. C, The surgical specimen. D, Postoperative chest radiograph showing complete expansion of the right lung.

At thoracotomy (J. F. D.) through the fifth right intercostal space the findings were as follows:—

1. A large cyst (9 × 5 cm.) high in the posterior mediastinum enveloped the right main bronchus with which it communicated posteriorly. The cyst was removed and the hole in the bronchus was repaired.
2. A second cyst (4 × 2·5 cm.) lying loosely attached to the lower oesophagus was removed.
3. A third cyst was just visible protruding through the posterior part of the diaphragm. This was left.

There were considerable respiratory problems postoperatively which required a tracheostomy, but the patient eventually recovered satisfactorily.

In view of these findings and the abdominal enlargement it was surmised that an abdominal duplication was also present although it could not be demonstrated by palpation or radiographic examination. A laparotomy was undertaken 10 weeks later (A. J.). From a point 15 cm. from the duodenojejunal flexure a duplication was closely applied to the jejunum for a distance of 75 cm. It lay in the mesentery and its upper end ran upwards to the oesophageal hiatus retroperitoneally (*Fig.* 4). Both ends were blind. The duplication was removed along with the attached bowel and the child made an uneventful recovery.

He has remained well with no thoracic, abdominal, or neurological problems.

Pathological examination showed that the thoracic cysts were lined with columnar and squamous epithelium, some of which had a typical gastric pattern with ulceration in one area. Smooth muscle in the wall was infiltrated with inflammatory cells, granulation tissue, and fibrous tissue. The jejunal duplication had two layers of smooth muscle in the wall and was lined with ciliated columnar and transitional epithelium.

Case 3.—W. K., aged 2 years, was admitted with a 3-month history of fever and a cough which had not responded to antibiotics. A chest radiograph showed a left lower-lobe shadow and primary tuberculosis was suspected. An additional finding, however, was the presence of anomalies of the upper dorsal vertebrae with widening of the interpedicular spaces. Further radiographs showed the mass to be in the posterior mediastinum and the combination of these radiological features supported the alternative diagnosis of an enteric cyst.

At thoracotomy (J. F. D.) through the fifth left intercostal space a spherical cyst, 5 cm. in diameter, projecting forwards from the 4th, 5th, and 6th vertebrae was noted and removed. Postoperative recovery and follow-up were satisfactory.

Pathological examination showed an ovoid cyst containing mucoid fluid with patchy representation of circular and longitudinal muscle in its wall and a gastric mucosal lining with oxyntic cells.

Case 4.—H. B. presented with the problem of chronic constipation at the age of 5 years. Examination revealed a massive abdomen with signs of intestinal obstruction (*Fig.* 5). Abdominal radiographs supported the clinical findings, a few fluid levels being noted on the erect film. A barium-enema examination was reported as being normal. A chest radiograph showed a soft-tissue mass in the right upper mediastinum and anomalies of the bodies and posterior spines of the lower cervical and upper dorsal vertebrae. These findings were suggestive of a thoracic enteric cyst but in view of the presence of intestinal obstruction laparotomy was undertaken first.

At operation (A. J.) a large tubular duplication over 100 cm. long and 7 cm. in diameter was found. The duplication lay in the mesentery, was blind at both ends, and extended from the mid-jejunum to the mid-ileum. It was resected along with the attached bowel, the child being left with about 160 cm. of residual small bowel. Postoperative recovery was uneventful.

Three months later thoracotomy was undertaken (J.F.D.) through the fifth right intercostal space. A thick-walled cyst, 10 × 5 cm., was found lying posteriorly in the upper mediastinum. It had a pedicle which ran into a large defect in the side of an anomalous vertebral body. Further dissection revealed that it was actually two cysts, one containing cerebrospinal fluid (anterior meningocele) and the other mucoid material (enteric cyst). Both cysts were removed and a small leak of cerebrospinal fluid was controlled by the application of a patch of muscle. A good recovery followed.

There was no communication between the thoracic and abdominal cysts. All three cysts had a wall of smooth muscle. Whereas the meningocele was lined with collagenized fibrous tissue with no epithelial lining, the enteric cysts were lined with columnar and stratified epithelium, some of which was ciliated.

Case 5.—D. B. was admitted at the age of 6 months with recurrent episodes of a cough since birth. On examination he had tachypnoea with an audible wheeze and rhonchi in all areas. A chest radiograph showed a tubular shadow containing air and fluid which could be traced to below the level of the diaphragm and these findings were confirmed by a barium-meal examination. There was also an obvious anomaly of the upper dorsal spine (*Fig.* 6).

A single-stage thoraco-abdominal operation was performed, entering the chest through the fifth right intercostal space and the abdomen through a right paramedian incision (A. J.). There was a tubular posterior mediastinal duplication. Its upper blind end extended into the root of the neck. Distally the duplication pierced the diaphragm in the region of the crura and extended retroperitoneally behind the pancreas and duodenum to enter the small-bowel mesentery and join with the jejunum end to side about 15 cm. below the duodenojejunal flexure. The duplication was removed without sacrificing any of the jejunum and a Meckel's diverticulum was also removed. Postoperatively there was some degree of ileus but eventual recovery was satisfactory.

Pathological examination showed two muscle coats and a gastric mucosal lining with oxyntic cells but there was also some duodenal and squamous epithelium. There were neurons in some intermuscular areas but in others compact aganglionic fibres were noted.

Case 6.—J. U. was admitted a few days after birth with a history of respiratory distress with intercostal recession. A chest radiograph showed a mass in the right side (*Fig.* 7 A) without an obvious vertebral anomaly. A barium-meal examination was normal. The symptoms steadily got worse until operation (J. F. D.) at the age of 6 weeks (right thoracotomy through the bed of the sixth rib). A bilobar cyst, 11 × 5 × 7·5 cm. (*Fig.* 7 B), was lying retropleurally in the right paravertebral gutter with the azygos vein lying across its waist. One hundred and sixty ml. of mucoid fluid were aspirated from the cyst which was closely applied to the oesophagus and descending aorta with numerous vascular adhesions. The cyst was removed with some difficulty (*Fig.* 7 C) but it had no obvious connexion with the spinal column. Postoperative recovery was uneventful (*Fig.* 7 D).

Pathological examination demonstrated that the cyst wall consisted of two layers of intestinal muscle and a muscularis mucosa but the mucosal lining was not evident and had presumably been destroyed.

DISCUSSION

The 6 cases described in this paper illustrate the varied spectrum as regards symptomatology, radiological anatomy, and surgical anatomy in cases of thoracic enteric cysts and diverticulae.

The clinical presentation was primarily as a respiratory problem in some cases but in others abdominal symptoms were predominant; occasionally respiratory and abdominal symptoms were present in the same patient.

The respiratory symptoms were commonly dyspnoea and cyanosis, recurrent bronchitis or pneumonia, and haemoptysis in 1 case. In the 2 neonates (*Cases* 1 and 6) there was severe respiratory distress and it may be difficult to differentiate such cases from congenital diaphragmatic hernia (Ravitch and Sabiston, 1962). It is important that these patients be operated upon as a matter of some urgency as the respiratory problem is liable to be aggravated with increasing accumulation of fluid in the cyst.

Case 3 presented with recurrent bronchitis and was the only case with an enteric cyst in the left side of the chest. Although tuberculosis had been suspected, localization of the mass to the posterior mediastinum in association with a spinal anomaly clinched the diagnosis. *Case* 5 also presented with a history of recurrent bronchitis since birth. Presumably mucous secretions produced by the tubular diverticulum discharged spontaneously into the jejunum with which it communicated, thereby preventing development of acute respiratory symptoms.

Case 2 presented primarily with abdominal symptoms at the age of 2 years, although there had been recurrent episodes of respiratory infections since birth. By the time he came to surgery a year later respiratory symptoms overshadowed the persisting abdominal problem. The occurrence of haemoptysis as a complication of thoracic enteric cyst has been reported previously (Ravitch and Sabiston, 1962), but because of extensive damage to the lung from peptic ulceration lobectomy may sometimes be necessary (Le Roux, 1962). The diagnosis in our case was delayed and illustrated the difficulty that may arise in differentiating haemoptysis from haematemesis in the paediatric age-group. It seems advisable that apart from radiological evaluation of the chest and spine such cases should be subjected to oesophagoscopy as well as bronchoscopy to enable an earlier diagnosis to be made. Melaena was a late manifestation in this case although occult blood had been noted in the stool some months earlier. A thoraco-abdominal duplication may, however, present primarily with alimentary-tract bleeding, as has been reported frequently (Davis and Barnes, 1952; Beardmore and Wiglesworth, 1958).

Cases 2 and 4 demonstrated the association of extensive intra-abdominal duplications with separate thoracic lesions and also emphasized the need to consider intestinal duplication in the differential diagnosis of abdominal enlargement in childhood. The importance of radiological evaluation of the chest and spine in patients with abdominal duplication is illustrated. In 1 case the thoracic cyst was asymptomatic and similar cases have been observed by several writers (Fallon, Gordon, and Lendrum, 1954; Forshall, 1961).

The radiological features of the 6 cases form an interesting study. A posterior mediastinal shadow in a child with respiratory symptoms but occasionally with only abdominal symptoms is usually the first positive finding. Apart from being aware of the possible 'enteric' origin of the mass, the most important supportive investigation is radiological evaluation of the spine. The mediastinal shadow may contain air if a communication exists with some part of the alimentary tract (a diverticulum) and this may be demonstrated by radio-opaque studies which should always be performed.

Spinal radiographs were normal in 1 of our cases but in the others there was an anomaly which ranged from a single hemivertebra to a complex anomaly of the cervicodorsal spine. Veenaklass (1952) advised tomograms to demonstrate the spinal defect. Beardmore and Wiglesworth (1958) pointed out that the cysts may be considerably caudal to the vertebral anomaly and may therefore be missed on routine radiographs. In our cases, however, the anomalous spine and the cysts were in close proximity although they did extend caudally to a variable degree.

Thoracic enteric masses are not common. Morrison (1958) found only 15 out of 1055 published cases of mediastinal masses to be enteric in origin and 5 of his 6 cases of enteric cysts were in the paediatric age-group. In a review of mediastinal masses in childhood, Haller, Mazur, and Morgan (1969) found 10 out of 80 cases to be enteric in origin and Ravitch and Sabiston (1962) have quoted similar figures.

According to the operative findings the clinical material reported in this paper can be divided into three groups:—

1. Prevertebral thoracic enteric cysts (*Cases* 3 and 6).
2. Prevertebral thoracic enteric cysts with abdominal duplications in the same patient (*Cases* 2 and 4).
3. Communicating thoraco-abdominal enteric diverticulae (*Cases* 1 and 5).

The non-communicating thoracic cysts, with increasing accumulation of mucous secretions, are likely to enlarge with corresponding deterioration in the clinical picture. This is not usually observed with bronchogenic mediastinal cysts which are usually diagnosed later in life (Ravitch and Sabiston, 1962). As the cyst enlarges it may eventually burst or erode into the lung or the bronchus, when the patient will present with chest pain or haemoptysis.

In the communicating thoraco-abdominal diverticulae air and barium-filled segments were seen on chest radiographs. In both the cases described the diverticulum was tubular and joined the jejunum end to side, as in the original description by Gross, Neuhauser, and Longino (1950). Barlow (1965) described in detail the surgical anatomical course taken by such a case. Elwood (1959) described the autopsy findings in a similar case in a neonate with the stump of the diverticulum attached to the spinal cord. This and similar cases in the literature and the association of a large anterior meningocele with the enteric cyst in *Case* 4 are understandable if it is accepted that they are of common derivation as part of the split notochord syndrome. Such an association has also been observed in duplications of the anal canal (Smith, 1969).

Now, to simplify treatment of pseudomonas urinary infections:

Pyopen

Penicillin safety and a published 76% success rate in 543 patients of varying renal status confirm Pyopen as a simple solution to a difficult problem.

For patients with normal kidneys 5G. 6 hourly is easily given using Pyopen infusion. For patients in renal failure or with impaired renal function a simple dosage of 2G. 8 hourly, by infusion or into the dialysate, is often sufficient.

Whether the kidneys are impaired or not, Pyopen provides the answer in pseudomonas urinary tract infections.

Adult dosage: Chronic urinary tract infection: 5G. 4–6 hourly
Acute uncomplicated infections: 2G. 6 hourly
Contra-indications: Penicillin hypersensitivity.
Side-effects: As with other injectable penicillins. In rare cases spontaneous skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen–by infusion or injection

Further information is available on request.

'KEEPING THE STERILE FIELD STERILE

—that is the objective of patient drapes in theatre

BARRIER* Theatre Drapes — unlike absorbent cotton drapes — are treated to resist strike-through of fluids — thus reducing the risk of bacterial transfer to the open wound.

BARRIER* Theatre Drapes also provide a number of other advantages:—

- ✱ Drapes are folded, cuffed and marked for convenient, aseptic handling.
- ✱ A full range of both composite and single item drape sets are available for the majority procedures.
- ✱ Presented in both sterile form and for inclusion in hospital prepared packs.
- ✱ Complemented by an advanced and unique drape system of absorbent/repellent adhesive towels.
- ✱ Completely disposable, reducing the work load in service departments and eliminating associated laundry problems.

now incised and the phrenic veins entering the inferior vena cava were secured. The suprahepatic inferior vena cava was temporarily clamped and divided just above the diaphragm.

At this stage the specimen was retained only by the ureter, the lower inferior vena cava, and the aorta, and the liver was well cooled by the perfusion. The crura were split and the thoracic aorta was exposed. Intercostal arteries were secured and the aorta was cut across obliquely with an anterior bevel about 2 cm. above the coeliac origin. The ureter and lower cava were divided and the specimen was freed. The last 500 ml. of perfusate with added papaverine (50 mg.) were injected into the aorta to flush out the kidney and pancreas; care was taken to avoid introducing air. The aortic cannula was removed and the aorta was ligated at its lower end, but the portal cannula was left in place to facilitate identification of the collapsed portal vein (*Fig.* 7).

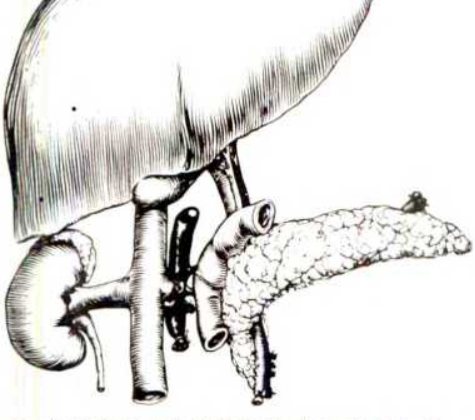

FIG. 7.—A specimen excised from the donor for simultaneous orthotopic transplantation of the pancreas, liver, and kidney.

Recipient.—This is very similar to that described for the orthotopic liver and pancreas transplantation, except that the additional transplantation of the kidney required that the inferior vena caval anastomosis was performed caudal to the renal veins and the recipient's kidneys were removed. The ureter was anastomosed obliquely end to end with a running 0000 chromic catgut suture. The aortic segment containing the orifices of the coeliac, the superior mesenteric, and the right renal arteries was anastomosed to the recipient aorta above the renal vessels end to side with a running 0000 silk suture (*Fig.* 8).

RESULTS

There were survivors following all the operative procedures described above. Some of the details are summarized in the tables.

1. Heterotopic Liver Transplantation (*Table I*).—Of the 6 allografted animals, 2 survived under a week. The grafts showed mononuclear-cell infiltration. The 4 remaining animals survived between 78 and 525 days. Early biopsies showed liver-cell atrophy and mononuclear-cell infiltration. The 3 animals surviving more than 500 days had completely absorbed the liver allografts which could not be found at autopsy.

2. Heterotopic Cardiac Transplantation (*Table II*).—The 3 animals survived for between 6 and 47 days. The 2 that died at 6 and 7 days after transplantation had marked changes of rejection. The animal that lived 47 days had the cardiac allograft biopsied at 7 and 18 days. On each occasion there was slight mononuclear-cell infiltration. At autopsy at 47 days there was marked cellular infiltration and aneurysmal dilatation of the left ventricle.

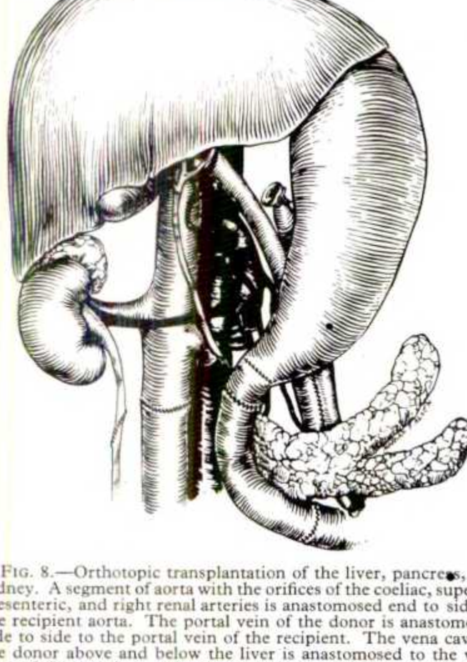

FIG. 8.—Orthotopic transplantation of the liver, pancreas, and kidney. A segment of aorta with the orifices of the coeliac, superior mesenteric, and right renal arteries is anastomosed end to side to the recipient aorta. The portal vein of the donor is anastomosed side to side to the portal vein of the recipient. The vena cava of the donor above and below the liver is anastomosed to the vena cava of the recipient. The ureter of the donor is anastomosed to the ureter of the recipient obliquely. The second part of the donor duodenum is anastomosed to the first and third parts of the recipient duodenum. Biliary and pancreatic drainage is into the donor second part of the duodenum. Vagotomy and pyloroplasty have been performed.

3. Heterotopic Heart and Liver Transplantation from Same Donor (*Table III*).—The 4 animals survived for between 7 and 203 days. The 2 that died at 7 and 22 days had changes of rejection in both the heart and liver allografts. The liver allograft was removed after 6 days in the animal which lived for 69 days, at which time there were changes of rejection in both the liver and the cardiac allografts. The 69-day autopsy showed marked changes of rejection with necrosis of the myocardium. The animal that lived for 203 days had the liver allograft removed at 15 days, at which time both the liver and heart allografts had marked changes of rejection. Similar changes were shown in a biopsy of the heart allograft at 36 days. At autopsy the heart had been completely absorbed.

4. Orthotopic Renal Transplantation.—Thirty grafts were performed and these were examined between 5 and 33 days after operation; 29 showed moderate to severe macroscopical and microscopical features of rejection. One allograft had a normal appearance after 12 days.

5. Heterotopic Liver and Orthotopic Kidney Transplantation from the Same Donor (*Table IV*).—Three animals died within a week. One of these died from rejection of the kidney; the liver was removed after 2¼ hours in the recipient. The animal that lived for 4 days had the liver allograft removed after 24·hours. The kidney at autopsy had slight mononuclear-cell infiltration. The animal that lived for 6 days had moderate mononuclear-cell infiltration of the liver and slight infiltration of the kidney. One animal died at 23 days with rejection changes in both the liver and kidney allografts. One animal in which the liver was removed after 24 hours died from uraemia with rejection of the kidney after 55 days. One animal lived for 95 days, dying of peritonitis. The liver was removed after 14 days, when it showed considerable mononuclear-cell infiltration. The renal biopsy at that time was normal. At autopsy, however, the kidney had substantial mononuclear-cell infiltration. Two animals are alive after 2½ and 3¼ years. The first of these had the liver allograft removed after 24 hours and is now surviving on the renal allograft. The second had a biopsy of both allografts at 20 days and there was moderate mononuclear-cell infiltration in the kidney and slight infiltration in the liver. Further biopsy at 96 days showed slight mononuclear-cell infiltration of the liver and a normal appearance of the kidney. Biopsy at 581 days showed marked atrophy and fibrosis of the liver and occasional foci of mononuclear cells in the kidney which was providing normal renal function.

Table I.—RESULTS OF HETEROTOPIC LIVER TRANSPLANTATION

PIG	SURVIVAL (days)	CAUSE OF DEATH	HISTOLOGY
1	4	Intestinal obstruction	Considerable mononuclear-cell infiltrate
2	6	Intestinal obstruction	Moderate mononuclear-cell infiltrate
3	78	Intestinal obstruction	Centrilobular degeneration—moderate mononuclear-cell infiltrate
4	512	Killed. Allograft absorbed	Biopsy of allograft at 38 days showed liver-cell atrophy and moderate mononuclear-cell infiltrate
5	519	Killed. Allograft absorbed	Biopsy of allograft at 105 days showed liver-cell atrophy, severe chronic vascular lesions. Moderate mononuclear-cell infiltrate
6	525	Killed. Allograft absorbed	Biopsy of allograft at 55 days showed substantial mononuclear-cell infiltrate. Biopsy at 138 days showed liver-cell atrophy and slight mononuclear-cell infiltrate

Table II.—RESULTS OF HETEROTOPIC CARDIAC TRANSPLANTATION

PIG	SURVIVAL (days)	CAUSE OF DEATH	HISTOLOGY
1	6	Killed	Marked mononuclear-cell infiltrate. Necrosis of heart muscle. Fibrinous pericarditis. Endocardial thrombus
2	7	Killed	Marked mononuclear-cell infiltrate. Necrosis of heart muscle
3	47	Killed	Biopsy at 7 days: Slight mononuclear-cell infiltrate Biopsy at 18 days: Slight mononuclear-cell infiltrate Autopsy at 47 days: Marked mononuclear-cell infiltrate. Aneurysm of left ventricle

Table III.—RESULTS OF HETEROTOPIC HEART AND LIVER TRANSPLANTATION FROM THE SAME DONOR

PIG	SURVIVAL (days)	CAUSE OF DEATH	HISTOLOGY	
			Heart	Liver
1	7	Gastric haemorrhage	Slight mononuclear-cell infiltrate. Some areas of degenerate muscle	Moderate mononuclear-cell infiltrate
2	22	Cardiac arrest	Biopsy at 8 days: Substantial mononuclear-cell infiltrate Autopsy: Moderate mononuclear-cell infiltrate	Moderate mononuclear-cell infiltrate. Severe liver-cell atrophy Moderate mononuclear-cell infiltrate. Severe liver-cell atrophy
	69	Killed	Biopsy at 6 days: Moderate mononuclear-cell infiltrate. Areas of degenerating muscle Autopsy: Substantial mononuclear-cell infiltrate. Extensive muscle necrosis	Removal at 6 days showed substantial mononuclear-cell infiltrate
4	203	Gastric haemorrhage	Biopsy at 15 days: Moderate mononuclear-cell infiltrate Biopsy at 36 days: Moderate mononuclear-cell infiltrate Autopsy: Heart absorbed	Removal at 15 days showed substantial mononuclear-cell infiltrate

6. Heterotopic Pancreatic Transplantation (*Table V*).—Four animals survived for between 16 and 49 days. The longest survivor had slight mononuclear-cell infiltration in the pancreatic allograft, as did the animal that survived 16 days. The graft in the 22-day survivor was infected. The animal that died after 37 days was emaciated and had an infarcted allograft. The control animals which had pancreatectomy alone became ill after a week, suffered great weight-loss, and died emaciated with ketosis. Of 5 control pancreatectomies, the longest survival was 26 days.

7. Orthotopic Pancreatic Transplantation (*Table VI*).—Four animals survived for between 2 weeks and 50 days. The animal that lived for 14 days died from bronchopneumonia with haemorrhagic pancreatitis. The other animals had moderate mononuclear-cell infiltration of the pancreas. The longest survivor died emaciated with necrosis and atrophy of the pancreatic parenchyma in addition to the cellular infiltration.

PIG	SURVIVAL (days)	CAUSE OF DEATH	HISTOLOGY	
			Kidney	Pancreas
1	11	Uraemia	Severe mononuclear-cell infiltrate Stigmata of severe rejection	Slight to moderate mononuclear-cell infiltrate

8. Orthotopic Kidney and Pancreas Transplantation from the Same Donor (*Table VII*).—One animal survived for 11 days, dying of uraemia with severe mononuclear-cell infiltration of the kidney indicating marked rejection. The pancreas, however, showed slight to moderate mononuclear-cell infiltration.

9. Orthotopic Transplantation of the Pancreas and Liver (*Table VIII*).—One animal survived for 38 days, dying of intestinal obstruction. The liver at autopsy showed slight mononuclear cell infiltration and portal-tract fibrosis. The pancreas showed a minimal mononuclear-cell infiltrate and a slight increase in fibrous tissue.

10. Orthotopic Transplantation of the Liver, Pancreas, and Kidney (*Table IX*).—Eight animals survived for between 4 and 57 days. Six died from intestinal obstruction, 1 from a biliary fistula, and 1 from peritonitis. The longest survivor had normal histological appearances of the liver, pancreas, and kidney allografts. The two animals which died at 4 and 10 days had microscopical cholangitis in the liver allografts. In the remaining animals there was mononuclear-cell infiltration present in all the allografts but the liver and pancreatic grafts had less intense infiltration than the kidney grafts.

DISCUSSION

The purpose of this paper is to describe technical aspects of organ allografts in the pig that have not previously been published. It is clear that the pig is an excellent experimental animal for organ transplantation research and can survive even the extensive procedure of simultaneous orthotopic transplantation of the liver, kidney, and pancreas. Certain tentative conclusions about the rejection pattern of the various organs can be made. These experiments confirm the previous data from this laboratory showing that, in the pig, heart and kidney allografts are rejected more aggressively than the liver. Rejection of pancreatic allografts, whether orthotopic or heterotopic, appears to be slower and milder than that of the kidney or heart. The liver, whether allografted heterotopically or orthotopically, appears to slow down the process of rejection of other organs. This can be demonstrated after 24 hours' residence of an accessory liver allograft which is subsequently removed. In 1 experiment, however, where the accessory liver allograft was removed after 2½ hours, aggressive rejection of the kidney occurred. Accessory livers and hearts undergo severe atrophy which seems to be independent of rejection. Similar changes have been reported in other species with accessory grafts of these organs. Orthotopic liver grafts in the pig frequently show microscopical changes of rejection which disappear spontaneously after 3 to 4 weeks. Similar changes have been observed in the rejection pattern of the organ allografts reported in this paper. The data here show quite clearly that liver allografts in the pig exhibit an immunosuppressive effect against themselves and other donor tissue which varies in individual experiments but cannot be related to the amount of tissue grafted. In fact, transplantation of the liver and pancreas together appears to increase the immune reaction in the liver.

8	57	Intestinal obstruction	Liver: Normal Kidney: Normal Pancreas: Normal

Studies of glucose and insulin metabolism following pancreatic transplantation in the pig are reported elsewhere (Sells, Calne, Hadjiyannakis, and Marshall, 1972). It was found that apancreatic pigs developed hyperglycaemia and ketosis. Both orthotopic and heterotopic allografts prevent hyperglycaemia. The recipients of functioning orthotopic pancreatic allografts have normal glucose-tolerance curves with raised plasma-insulin levels, whilst the glucose-tolerance tests on heteroropic liver-graft recipients showed hypoglycaemia and there was marked hyperinsulinaemia. Denervation and ischaemic damage of the grafted pancreas could explain the high plasma-insulin levels. It is possible that the diversion of insulin and glucagon from the liver in the heterotopic grafts may have accentuated the hypoglycaemia.

PREDICTION OF 1-YEAR SURVIVAL AFTER RESECTION OF LUNG TUMOURS FROM THE PREOPERATIVE STEROID EXCRETION PATTERN

BY L. G. S. RAO*

PSYCHOSOMATIC RESEARCH UNIT, DEPARTMENT OF PSYCHOLOGICAL MEDICINE, SOUTHERN GENERAL HOSPITAL, GLASGOW

SUMMARY

A prospective study of 50 patients with lung cancer who were treated by surgical resection of their tumour has shown that most of those who died within 1 year after resection had abnormalities in preoperative steroid excretion whereas most of those who are alive had normal steroid excretion. Of the 21 patients who died within 1 year, 5 died in hospital, mainly as a result of surgical complications, and were found to have an abnormally low androsterone to aetiocholanolone ratio and a high total 17-oxosteroid excretion. Those who were discharged alive and well from hospital but who died within 1 year as a result of metastasis to other organs had a low androsterone level in relation to aetiocholanolone and to total 17-hydroxycorticosteroids. Thus, it has been possible to identify by their preoperative steroid excretion 12 out of 14 patients who died within 1 year although they had had a successful resection.

ALTHOUGH radical surgery offers the best chance of survival for patients with lung cancer compared with other methods of treatment, nearly half of the surgically treated patients die within 1 year. Therefore a method of prediction of the prognosis might be useful for the management of these patients. If the technique of prediction has a biochemical basis it might provide clues to the pathogenesis of this disease and might even lead to a therapeutic application. Such a chemical method of predicting prognosis has already been shown to be effective for patients with inoperable lung cancer (Rao and Hewit, 1970). The present report deals with the prognosis of patients whose lung tumours have been resected by a lobectomy or pneumonectomy.

PATIENTS AND METHODS

Fifty male patients, aged 36–68 years (mean 55·7 years), who had undergone a resection of their lung tumour were followed up for a period of at least 1 year from the date of surgery; 27 had had a pneumonectomy and 23 a lobectomy. Two early morning specimens of urine had been collected for steroid assay about 3 days before surgery. Details of patients and laboratory methods have been described elsewhere (Rao, 1970).

RESULTS

Twenty-one patients died within 1 year after resection and, of these, 5 died in hospital mainly as a result of surgical complications such as haemoptysis, peripheral shock, or pulmonary embolism (group 1). Of the remaining 16 patients, 2 died of heart failure and kidney failure 4 and 7 months respectively after surgery and had no obvious evidence of metastases. The remaining 14 patients left hospital after surgery in a reasonable condition but died within 1 year mainly as a result of metastasis to the other lung or to other organs (group 2). Twenty-nine of the patients were alive and most of these were well 1 year after resection (group 3). Steroid excretion before resection was compared in the three groups and showed some striking differences (*Table I*). Among the patients who died within 1 year, those who died in hospital showed some differences in steroid excretion compared with those who left hospital alive and well; the former patients had a lower androsterone (A) to aetiocholanolone (E) ratio than the mean for group 2, and they also had higher 17-oxosteroid (KS) and 17-hydroxycorticosteroid (17-OHcs) excretion levels compared with those in groups 2 and 3. Patients in group 2 had significantly lower excretion of A and E compared with that in group 3. In group 2, 12 out of 14 patients had a 17-OHcs : A ratio of more than 10, whereas in group 3 only 5 out of 29 patients had such a high ratio. Thus most of the patients in group 2 could be identified by their abnormal steroid excretion (*Fig.* 1). Two patients in group 2 died of heart failure and kidney failure respectively and these did not have any marked abnormalities in steroid excretion.

DISCUSSION

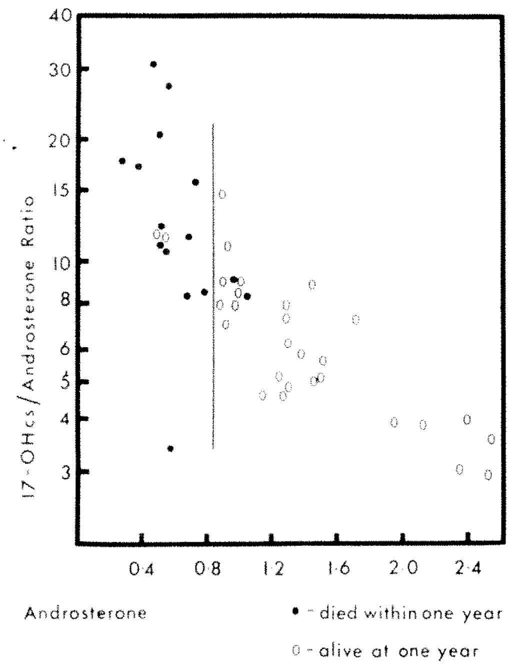

FIG. 1.—The survival of surgically treated patients.

Table I.—PREOPERATIVE STEROID EXCRETION IN GROUPS 1, 2, AND 3

GROUP	NO. OF PATIENTS	STEROID EXCRETION (mg. per g. creatinine per litre)			
		A	E	KS	17-OHcs
1	5	1·29 ± 0·46	2·90 ± 0·16*	7·02 ± 0·77	10·39 ± 3·56
2	16	0·72 ± 0·31*	1·19 ± 0·46*	4·18 ± 1·44*	8·26 ± 2·71
3	29	1·42 ± 0·66	2·11 ± 1·15	5·83 ± 1·93	8·11 ± 2·29

A, Androsterone; E, aetiocholanolone; KS, 17-oxosteroids; 17-OHcs, hydroxycorticosteroid.
* Significantly different from the mean of group 3 ($P < 0·01$).

The results indicate that it is possible to identify using a chemical method, even before surgical treatment, those lung cancer patients who have a poor prognosis despite resection of their lung tumours. The significance of these findings could be considerable in the management of these patients if it can be established that their abnormalities are of aetiological significance and are not merely a reflection of the stage of the disease. The latter possibility arises because in patients with inoperable lung cancer the same steroid abnormalities are significantly related to the prognosis (Rao and Hewit, 1970). Thus, in these patients the greater the 17-OHcs : A ratio the shorter is the survival time. The present results show that this ratio is equally useful in predicting the 1-year survival in patients whose lung tumours have been surgically removed. Therefore, it is possible that the 17-OHcs : A ratio indicates the presence of metastases which were not clinically recognizable, and thus reflects only the stage of the disease. An alternative possibility in surgically treated patients is that a high 17-OHcs : A ratio indicates a greater susceptibility to metastasis after surgery. Previous work (Rao, 1970) has shown that removal of the lung tumour does not result in the disappearance of these steroid abnormalities and therefore they cannot be considered as being due to the presence of the lung tumours. It is not likely that these abnormalities are the effects of the clinically unrecognizable secondary tumours, since the removal of the primary tumour did not result in the decrease of the abnormalities. Therefore it appears that these abnormalities in lung cancer are the characteristics not of the tumour but rather of the host, which may be involved in the defence against the growth and spread of the tumour. Some indications are already available of the possible ways in which steroid abnormalities may be involved in the defence mechanisms of the host against the tumour. These can be considered under three main aspects.

1. Metabolic Effects.—Corticosteroids are mainly catabolic (Symington, 1969) and androsterone is anabolic (Furman and Howard, 1959). The high 17-OHcs : A ratio found in patients with a poor prognosis might shift the metabolic balance towards increased catabolism and lead to the cachexia found in many patients with a poor prognosis.

2. Haemostatic Effects.—It is known that cancer patients have an increased coagulability of their blood and this has been suggested as favouring the establishment of blood-borne metastasis (Thornes, 1967). Evidence for this view has come from the finding that the death-rate from cancer among persons receiving anticoagulant therapy is significantly lower than that in the general population (Thornes, 1967). It is known that corticosteroids increase coagulation by increasing the free fatty acids in the blood (Hoak and Robinson, 1963), whereas androsterone reduces coagulation by its ability to reduce platelet stickiness (Dufault, Tremblay, Nowaczynski, and Genest, 1961) and to increase fibrinolysis (Thornes, 1970). In fact, androsterone has been used prophylactically for this purpose in cardiovascular disease. Aetiocholanolone administration results in the increase of fibrinogen (Kimball, Vogel, Perry, and Wolff, 1967) and may thus enhance the tendency to coagulation. Thus, the low A : E ratio found in patients with a poor prognosis might have resulted in increased blood coagulation, favouring the establishment of blood-borne metastasis. Increased coagulability may also result in the formation of fatal pulmonary emboli.

3. Immunological Effects.—The importance of immunological mechanisms in the defence against cancer is now widely recognized (Editorial, *British*

Medical Journal, 1970). The immunosuppressive effects of corticosteroids are well known and these steroids are used extensively for this purpose in tissue transplantation. It is likely that androsterone may enhance the immune response because of its anabolic effects. Thus, the high 17-OHcs : A ratio seen in patients with a poor prognosis may lead to a reduced immune response against the tumour.

It must be emphasized that although the above mechanisms are discussed separately two or more of these may be operating in unison to enhance the effect of steroid abnormalities. A careful investigation of these mechanisms in the prognosis of cancer would be a rewarding study.

A convincing method of proving that the steroid abnormalities in lung cancer are of aetiological significance would be to study the effects of correction of these abnormalities on the prognosis of these patients. Since the abnormalities in steroid excretion centre around a deficiency of androsterone these could be corrected by the administration of this steroid or a suitable precursor. Testosterone would not be a suitable steroid because the A : E ratio is not altered by its administration (Johnsen, 1968). Dehydroepiandrosterone also would not be a suitable precursor because this steroid is converted mainly to aetiocholanolone and thus would increase the abnormality found in lung cancer (Kirschner and Lipsett, 1964). It may therefore be necessary to administer androsterone or some other 5-alpha-androstane compound. Since the correction of the deficiency of androsterone could be carried out in conjunction with the existing methods of therapy it should be entirely feasible to conduct such a clinical trial.

INVESTIGATION OF OEDEMA OF THE LOWER LIMB FOLLOWING SUCCESSFUL FEMOROPOPLITEAL BY-PASS SURGERY: THE ROLE OF PHLEBOGRAPHY IN DEMONSTRATING VENOUS THROMBOSIS

BY J. D. HAMER
QUEEN ELIZABETH HOSPITAL, BIRMINGHAM

SUMMARY

Of 21 limbs having successful femoropopliteal vein by-pass grafts, 20 showed peripheral oedema 7 days after operation. Circumferential enlargement of more than 4·5 cm. was associated with thrombosis of the popliteal or tibial veins, whereas legs enlarging less than 1·5 cm. did not show radiological evidence of venous thrombosis.

Venous thrombosis is less likely after surgery for intermittent claudication than for rest pain or gangrene of the toes.

Distal anastomosis of the vein-graft to the popliteal artery is more often accompanied by venous thrombosis than anastomosis above the knee-joint.

OEDEMA of the leg and foot following successful reconstructive surgery to the arteries of the lower limb has been observed ever since such procedures were introduced (Eastcott, 1953; Rob, 1953). Whereas hyperaemia occurs after reconstruction of both aorto-iliac and superficial femoral segments, appreciable peripheral oedema appears to be most frequently encountered after surgery to the femoral and popliteal arteries. Peripheral oedema is not necessarily associated with hyperaemia and in such cases it is possible that lymphatic or venous occlusion may be contributory factors.

Damage to large lymphatic trunks accompanying the long saphenous vein has been described in patients having femoropopliteal vein by-pass grafts and a close correlation was found between the presence of oedema and lymphatic occlusion (Vaughan, Slavotinek, and Jepson, 1970). Husni (1967) was unable to confirm an association between oedema and deep-vein thrombosis.

The present investigation has been undertaken in order to determine the true incidence of oedema after femoropopliteal reconstructions, and by means of a precise technique of phlebography to study the incidence of thrombosis within the tibial, popliteal, and femoral veins.

EXPERIMENTAL PROTOCOL AND METHODS

Twenty-two consecutive patients undergoing autogenous saphenous by-pass grafting for atherosclerotic occlusive disease of the superficial femoral artery have been studied.

Several techniques for detecting the presence of venous thrombosis are available and the suitability of each has been considered in the context of this investigation. Preferential localization of ^{125}I- and ^{131}I-labelled fibrinogen in venous thrombi is well documented but is unsuitable for detecting thrombosis in the vicinity of a surgical operation in view of the deposition of isotope in fibrin laid down during the early stages of wound healing, leading to a 'blurred' scan. The ultrasonic 'Doppler-effect' flowmeter has been widely used to measure femoral venous flow by Sigel, Popky, and Boland (1967) and Sumner, Baker, and Strandness (1968), but this technique is less reliable in its present stage of development for demonstrating flow in venous plexuses such as those related to the soleus muscle. Such techniques as infra-red photography (thermography) and plethysmography are not sufficiently precise to allow demonstration of thrombosis in the small deep veins in the leg.

For these reasons phlebography appeared to be the most appropriate technique for use in this study. The rationale of the investigation and its risks were fully discussed with all the patients consenting to take part in the study.

Technique of Phlebography.—Phlebography was performed on the seventh postoperative day, oedema related to the surgical procedure rarely appearing later than this. Dietary intake on the morning of the investigation was restricted to fluids in order to minimize the tendency of contrast media to induce nausea. The technique employed was that described by Rogoff and De Weese (1960) and modified by Wesolowski, Greenfield, Sawyer, Fries, Shaefer, and Martinez (1965).

Hypaque 45 per cent (Bayer) was employed as the contrast medium and was introduced by direct transcutaneous venepuncture on the dorsum of the foot, facilitated by the placement of a tourniquet just above the ankle. 'Cut-down' exposure of a superficial vein is entirely unethical in a potentially ischaemic foot, and in this series direct venepuncture was perfectly satisfactory on each occasion. The leg under investigation was held in steep dependency at 45° downwards. Many authors attribute poor opacification of the deep veins to failure in observing this particular point. Retrograde venous flow was also encouraged by the use of the Valsalva manœuvre. A tourniquet, 8·0 cm. in width, was placed just above the ankle and inflated to 80 mm. Hg in order to direct the venous blood-flow from the dorsum of the foot into the deep veins of the calf. Radiographs were taken in both the anteroposterior and lateral planes.

The protocol in this investigation included information with regard to the severity of symptoms and the existence of coexisting disease such as diabetes mellitus or superficial thrombophlebitis, and, in addition, the exact position of proximal and distal artery-to-vein anastomosis was recorded.

The result of each operation at the seventh postoperative day was recorded according to the following grading:—

A. Restored tibial pulses.
B. Graft pulsatile but no tibial pulses.
C. Foot warmer but graft not palpable.
D. Graft palpable but not pulsatile.
E. Foot worse.

The circumference of both legs was measured before operation and again on the seventh postoperative day 25 cm. above and 20 cm. below the tubercle of the tibia. Although it has been found possible to measure limb circumference to an accuracy of ± 0·2 cm., measurements have been recorded to the nearest 0·5 cm.

RESULTS

Clinical details of the 22 patients studied are summarized in *Table I*. The result of surgery in each limb studied was very satisfactory, being graded A or B, thus eliminating immediate graft failure as a possible cause for oedema.

Surgery was undertaken for intermittent claudication in 12 limbs, rest pain in the foot in 6 limbs, and gangrene of the toes in 3 limbs. In 9 instances the lower anastomosis between the vein-graft and the artery was situated above the knee-joint and in 12 below the joint.

When measured on the seventh postoperative day 1 patient showed no difference in calf circumference in comparison with the contralateral limb, but the remaining 20 patients showed an increase on the operated side, with a range from 0·5 to 7·5 cm.

Venography performed on the seventh postoperative day showed no evidence of venous thrombosis in 12 patients but revealed occlusive or non-occlusive thrombosis in 9. No features suggesting pulmonary embolism occurred in these patients.

Relation of Oedema to Venous Thrombosis.—*Table II* includes the results from all the patients studied, placing each limb into one of five categories according to the severity of oedema. Eight limbs enlarged circumferentially by 0–1·4 cm., all being free from venous thrombosis. Clinical oedema was present above 1·5 cm. enlargement, but venous thrombosis occurred only twice with a circumferential increase of less than 4·5 cm. Seven limbs were found to have enlarged by more than 4·5 cm. and all showed popliteal or tibial venous thrombosis.

The importance of carrying out phlebography in both the lateral and anteroposterior planes was illustrated in several instances in which non-occlusive thrombus was clearly seen in one plane but not in radiographs taken at a right-angle.

Factors influencing Venous Thrombosis.—*Table III* relates presence or absence of venous thrombosis to the severity of preoperative limb ischaemia.

Of the 12 limbs in which intermittent claudication was the preoperative indication for surgery, only 4 subsequently developed venous thrombosis. Nine limbs showed more severe ischaemia, however, and postoperatively 5 of this group were found to have popliteal or tibial venous thrombosis.

Table IV compares the incidence of venous thrombosis with the level of anastomosis of the vein-graft to the popliteal artery.

Table I.—SUMMARY OF THE CLINICAL DETAILS

CASE	SYMPTOMS	LEVEL OF LOWER ANASTOMOSIS	RESULT OF OPERATION (Grade)	CIRCUMFERENCE DIFFERENCE 7 DAYS AFTER OPERATION (cm.)	RESULT OF VENOGRAM
1	Claudication: 100 yd.	5·0 cm. A.K.	A	Unchanged	Normal
2	Rest pain	1·0 cm. B.K.	B	4·5	Tibial thrombosis
3	Claudication: 150 yd.	2·0 cm. B.K.	B	0·5	Normal
4	Severe rest pain	Posterior tibial artery	B	6·5	Tibial thrombosis
5	Claudication: 150 yd.	2·0 cm. B.K.	B	6·0	Tibial thrombosis
6	Gangrene of toes	1·5 cm. B.K.	A	0·5	Normal
7	Claudication: 100 yd.	1·5 cm. A.K.	B	0·5	Normal
8	Gangrene of toe	2·0 cm. B.K.	B	7·5	Tibial and popliteal thrombosis
9	Claudication: 100 yd.	5·0 cm. A.K.	A	3·5	Tibial thrombosis
10	Claudication: 200 yd	0·5 cm. A.K.	A	0·5	Normal
11	Claudication: 100 yd.	2·0 cm. B.K.	A	4·5	Popliteal thrombosis
12	Claudication: 200 yd.	2·0 cm. A.K.	A	1·5	Popliteal thrombosis
13	Claudication: 100 yd.	1·0 cm. B.K.	A	1·5	Normal
14	Rest pain	0·5 cm. A.K.	A	0·5	Normal
15	Claudication: 100 yd.	3·0 cm. A.K.	A	1·0	Normal
16	Rest pain	0·5 cm. B.K.	A	6·0	Popliteal and tibial thrombosis
17	Gangrene	3·0 cm. B.K.	A	4·5	Popliteal thrombosis
18	Claudication: 60 yd.	6·0 cm. A.K.	B	1·0	Normal
19	Claudication: 100 yd.	2·0 cm. A.K.	A	3·0	Normal
20	Rest pain	3·0 cm. B.K.	A	2·0	Normal
21	Rest pain	2·5 cm. B.K.	A	1·5	Normal

A.K. = Above knee-joint; B.K. = below knee-joint. *See* text for explanation of grading.

Table II.—RELATION BETWEEN OEDEMA AND PRESENCE OF VENOUS THROMBOSIS

	INCREASE IN CALF CIRCUMFERENCE					TOTAL
	0–1·4 cm.	1·5–2·9 cm.	3·0–4·4 cm.	4·5–5·9 cm.	6·0–7·5 cm.	
Thrombosis	—	1	1	3	4	9
No thrombosis	8	3	1	—	—	12

Table III.—RELATION BETWEEN VENOUS THROMBOSIS AND SEVERITY OF PREOPERATIVE SYMPTOMS

	PREOPERATIVE SYMPTOMS			TOTAL
	Intermittent Claudication	Rest Pain	Gangrene	
Thrombosis	4	3	2	9
No thrombosis	8	3	1	12

Anastomosis above the knee-joint was carried out in 9 cases and was accompanied by thrombosis only twice. Twelve operations were carried out below the joint, however, and of these, 7 developed venous thrombosis.

None of the patients in this series was diabetic and there were no cases of existing superficial thrombophlebitis or pre-existing deep-vein thrombosis, as judged clinically. In all the cases the preoperative measurements of thigh and calf circumference showed no difference between the symptomatic and the contralateral limb.

DISCUSSION

The results of this investigation confirm that oedematous swelling of the leg below the knee may be expected 7 days after successful femoropopliteal by-pass grafting. It would appear that an increase in circumference of 0·5–1·5 cm. above the preoperative measurement is most unlikely to be associated with venous thrombosis. A circumferential increase of 4·5 cm. or more is, however, strongly suggestive of thrombosis in the tibial or popliteal veins.

Table IV.—RELATION BETWEEN THROMBOSIS AND LEVEL OF POPLITEAL ANASTOMOSIS

	LEVEL OF POPLITEAL ANASTOMOSIS		TOTAL
	Above Knee	Below Knee	
Thrombosis	2	7	9
No thrombosis	7	5	12

It would also appear that venous thrombosis occurs less frequently after surgery for the relief of intermittent claudication than for rest pain and ischaemic gangrene. Thrombosis was noted in 5 out of 9 limbs treated for severe ischaemia, whereas only 4 out of 12 limbs in the claudication group showed thrombosis.

The explanation for this apparent association between venous thrombosis and surgery for relief of severe symptoms may lie in the observation that thrombosis of the popliteal vein occurs more frequently following anastomosis of a vein-graft to the popliteal artery below the level of the knee-joint than after procedures concentrated above the joint. Distal dissection of the popliteal artery was necessary in 8 out of the 9 patients presenting with rest pain or gangrene.

Mobilization of the popliteal artery high in the popliteal fossa is generally less likely to involve trauma to the popliteal vein than more distal dissection.

As the popliteal artery descends through the popliteal fossa it is crossed posteriorly by the popliteal vein and medial popliteal nerve, the vein being closely applied to the artery. Using the medial approach to the fossa the artery is at its most accessible 4–5 cm. above the knee-joint, lying deep to the muscular portion of the semimembranosus just above the origin of the tendinous part of the muscle. At this point the popliteal vein can be separated from the artery with very little difficulty.

In contrast, adequate exposure of the popliteal artery below the knee-joint line, as it lies lateral to the medial popliteal nerve between the two heads of the gastrocnemius, is only possible after freeing the adherent vein together with the venae comitantes which so frequently accompany the distal portion of the artery. It is frequently necessary to divide one or two cross connexions of the venae comitantes to the main popliteal vein and care is necessary to avoid narrowing the vein at these points. Division of veins entering the popliteal vein from the surrounding muscles may also be necessary.

It is, therefore, likely that the critical factor leading to popliteal vein thrombosis is the level at which the lower end of the graft must be anastomosed to the popliteal artery.

Anastomosis of the vein-graft above the knee-joint also confers considerable advantages in terms of sustained patency compared with distal anastomoses (Baddeley, Ashton, Slaney, and Barnes, 1970). Thus it is clear that wherever possible the anastomosis of the vein-graft to the popliteal artery should be carried out above the knee-joint.

Although it would seem that marked oedema is commonly associated with venous thrombosis the aetiology of less obvious swelling remains obscure. Simeone and Husni (1959) associate oedema and hyperaemia after reconstructive surgery with changes in the physiological response of arterioles to increased intraluminal pressure. Controversy surrounds the understanding of the regulation of arterial tone. Bayliss (1902) suggested that the normal constrictor response of small arteries to increased intraluminal pressure depends on a local response of smooth muscle in the vessel wall to the stimulant action of each pulse wave. Following circulatory arrest, this response is lost as a consequence of functional failure of ischaemic smooth muscle. Anrep (1912) regarded post-ischaemic vasodilatation and oedema as manifestations of local release of vasodilator metabolites, but Folkow (1949) showed that vasodilatation can occur after arterial occlusion for periods of less than 3 seconds, rather vitiating a chemical cause for lack of smooth-muscle response. Essex, Herrick, Baldes, and Mann (1943) showed that muscle-cells in the walls of canine arteries exposed to reduced intraluminal pressure undergo atrophy. This work awaits clinical confirmation, but changes specific to ischaemia are very difficult to separate from the degenerative processes seen in atherosclerosis. It is thought that the prolonged low-flow state distal to a coarctation of the aorta leads to changes in peripheral vessels to the extent that, after resection of the coarctation aneurysm formation, non-specific arteritis and fibrinoid necrosis may involve peripheral arteries (Perez-Alvarez and Oudkerk, 1955).

Thus, evidence does exist that peripheral arteries may be incapable of a normal physiological response to restored intraluminal pressure following a prolonged period of reduced flow. Excessive transudation of fluid across capillary membranes consequent upon sustained elevation of capillary hydrostatic pressure, in the absence of pre-capillary arteriolar constriction, may contribute to peripheral oedema after successful reconstructive arterial surgery.

Although we are unable to comment upon the findings of Vaughan and others (1970) with regard to the contribution of lymphatic obstruction to leg oedema after femoropopliteal by-pass procedures, it seems probable that excessive extracellular fluid accumulates to a limited extent in response to impaired vasoconstrictor activity, but in patients with more marked swelling thrombosis of the tibial or popliteal veins must be considered.

Acknowledgements.—It is a pleasure to record my gratitude to Professor G. Slaney and Mr. F. Ashton who allowed me to study their patients and gave encouragement and helpful criticism. I am also indebted to colleagues in the X-ray Department of the Queen Elizabeth Hospital for their helpful co-operation.

Open weave gauze support backing.
Cotton/acrylic pad. Three times more absorbent than cotton wool.
Non-adherent film to protect wound. Perforated to allow exudate through.

Melolin. One dressing idea that really comes off.

Most dressings stick. And a pretty painful business it can be. But with Melolin the wound is protected by a non-adherent perforated film.

Exudate is taken through the perforations into an extra absorbent pad.

When you change the dressing it peels off. If you prefer, you can peel away the pad, leaving the film only on the wound.

Melolin comes individually wrapped (sterile) or in bulk.

Write for full information or ring Mrs E. Arthur, Welwyn Garden 25151.

Melolin is a registered trade mark of T. J. Smith & Nephew Limited.

Smith & Nephew Limited,
Bessemer Road,
Welwyn Garden City, Herts.

Prescribable on E.C. 10 as Perforated Film Absorbent Dressing (Drug Tariff).

Hospital medicine at its best.

IN BRONCHITIS early optimism confirmed by further clinical experience

“On the basis of our earlier experience,[1] we said of trimethoprim that ‘we believe it to represent a major discovery and to have far-reaching therapeutic possibilities.’ Not only have we had no subsequent reason to alter this belief, but in our view some very promising possibilities have yet to be explored.”[2]

More effective than ampicillin or tetracycline

In the reduction obtained in sputum volume and purulence SEPTRIN* has been shown to be superior to either ampicillin or tetracycline.[3,4]

Highly active against both primary and secondary invaders

“. . . not only are the two primary pathogens *Strep pneumoniae* and *H influenzae* sensitive, but so are secondary invaders such as klebsiella which often replace them after antibiotic treatment.”[2]

“It is seldom at the completion of a clinical trial that authors are inclined to classify an antimicrobial . . . , but in this case, on our results, we feel that the combination of trimethoprim plus sulphamethoxazole can only be considered excellent on the criteria originally specified, namely the elimination of the infecting microorganism.”[5]

SHORT NOTES OF RARE OR OBSCURE CASES

RECURRENT SPONTANEOUS RUPTURE OF THE URINARY BLADDER

By M. H. WHEELER*
SURGICAL UNIT, CARDIFF ROYAL INFIRMARY

SUMMARY

Only 5 cases of recurrent spontaneous bladder rupture have been reported in the literature. The present report is of a patient who developed a spontaneous rupture on two occasions within 5 years. The first rupture was treated without bladder suture. A pelvic fracture 12 months before the first episode is considered to be a probable aetiological factor.

SPONTANEOUS rupture of the urinary bladder is uncommon but recurrent spontaneous rupture is very rare. The present report is of a patient who developed a spontaneous rupture on two occasions within 5 years.

CASE REPORT

In January, 1968, Mrs. M. S., a 32-year-old housewife, was admitted to hospital as an emergency with severe generalized abdominal pain which had commenced suddenly 12 hours previously when she had risen from bed to micturate. She had failed to reach the toilet because of the severity of the pain and had subsequently been unable to micturate although she had felt the desire to do so. There was no history of recent trauma, excessive alcoholic intake, or other urinary symptoms.

On examination the patient was ill and in considerable pain. There was generalized abdominal tenderness and rigidity with absent bowel-sounds. A diagnosis of perforated abdominal viscus was made and a laparotomy was performed. Urine was found in the peritoneal cavity. There was a small circular perforation through a linear scar approximately 2·5 cm. in length on the posterior aspect of the bladder.

This perforation was closed in two layers with catgut and a Foley balloon catheter was inserted into the bladder per urethram. Ampicillin was prescribed for 1 week. The postoperative course was uneventful and a subsequent intravenous pyelogram and micturating cystogram were normal. The patient was discharged on the tenth postoperative day.

PAST HISTORY.—In March, 1962, the patient had been involved in a motor accident, suffering concussion, a fractured left tibia, and also fractures of the right horizontal and vertical pubic rami. At this time there had been no evidence of any injury to the urinary bladder and recovery had been uneventful.

Twelve months later in March, 1963, she had been admitted to another hospital with a history of severe generalized abdominal pain of sudden onset. A diagnosis of peritonitis secondary to a perforated peptic ulcer had been made and a laparotomy had been performed. At operation the only abnormal finding had been that of 300 ml. of slightly blood-stained fluid in the peritoneal cavity. The source of the fluid had not been established.

Postoperatively the patient had developed what had been thought to be ascites and at abdominal paracentesis 3·5 litres of straw-coloured fluid with a specific gravity of 1012 had been obtained. Cytology of the fluid had demonstrated numerous endothelial and squamous cells. At this stage a urethral catheter had been inserted because of suspected retention of urine. The ascites had regressed spontaneously, the catheter had later been removed, and the patient had recovered.

DISCUSSION

The first recorded case of spontaneous rupture of the urinary bladder was as long ago as 1279 by Pierus (Stone, 1931). Whenever spontaneous rupture occurs there is almost invariably a predisposing factor recognizable (*Table I*). Stone (1931) reviewed 40 cases and added 2 of his own. He stressed the importance of chronic or acute urinary obstruction and also of destructive lesions of the bladder as aetiological factors. Stone's second case was due to a vesical calculus eroding the bladder wall and possibly causing obstruction. A similar case was also reported by Innis in 1961.

Table I.—CAUSES OF SPONTANEOUS BLADDER RUPTURE

1. Obstruction
    - Prostatic hypertrophy (Thomas, 1956)
    - Papilloma (MacAlister, 1955)
    - Neurogenic
2. Scarring, inflammation, or malignant disease of the bladder wall (Altman and Horsburgh, 1966)
3. Over-distension, e.g., by alcohol (Feigal and Polzak, 1946)
4. Drugs, e.g., Carbachol (MacAlister, 1955)
5. Straining, e.g., stool, labour
6. Idiopathic

The commonest cause of urinary obstruction is prostatic hypertrophy and this has frequently been a factor in the causation of rupture. Prostatectomy has been carried out with success at the same time as the bladder repair (Thomas, 1956).

Over-distension of the bladder which is frequently associated with excessive alcoholic intake has also been recognized as a predisposing cause (Feigal and Polzak, 1946; Clinton-Thomas, 1955).

---

* Present address: Department of Clinical Surgery, University of Edinburgh.

Drugs used in the treatment of urinary retention may lead to bladder rupture and MacAlister in 1955 reported such a case with the use of Carbachol.

Hershman and Allen (1954) described a case of spontaneous rupture occurring in a patient suffering from syphilis. The authors felt that they had excluded a neurogenic bladder, however, from the cystoscopic and cystometric findings.

It has also been thought that spontaneous rupture may be precipitated by increased abdominal pressure, e.g., straining at stool and micturition or during labour. Graves (1960) recorded a case occurring during the 3rd month of pregnancy. Nevertheless, spontaneous rupture in the female is far less common than in the male.

Finally, the condition may occur without a predisposing cause. Such a case was reported by Barnes and Steele (1935).

Recurrent spontaneous rupture of the urinary bladder is a rare phenomenon. Crastnopol, Artz, and Rosett (1950) reviewed 3 cases and added 1 of their own. All 4 patients were male and in all the rupture was intraperitoneal. The patient of Crastnopol and others (1950) gave a history of pelvic trauma 27 months before rupture occurred, but they thought it justifiable to include this as a case of spontaneous rupture in view of the considerable time interval which had elapsed.

The patient of Bliss, Clark, and Saunders (1964) was a female who experienced two episodes of rupture after a subarachnoid haemorrhage. It was considered that there was retention with neuromuscular incoordination as an aetiological factor in the first instance and an epileptic fit in the second episode. Both ruptures in each of the 5 patients mentioned above were treated by suture and bladder drainage.

The case reported here is believed to have suffered recurrent spontaneous rupture of the urinary bladder. The first episode occurred 12 months after a motor accident which had resulted in a fractured pelvis. Although at the time of the first rupture the correct diagnosis was not made the exact nature of the illness is clear in retrospect. What was diagnosed as being ascitic fluid must have been urine in the peritoneal cavity. This rupture was therefore successfully treated by bladder drainage alone, but this is obviously not to be recommended as a method of management as a second rupture can occur later through a thin scar.

The present case is similar to the case reported by Crastnopol and others (1950) in that there was a history of pelvic trauma and a long delay before rupture occurred.

The correct management of spontaneous rupture consists of laparotomy, repair of the bladder—in two layers if possible—peritoneal toilet, adequate bladder drainage by means of urethral catheterization, and antibiotic cover.

The condition is still a serious one with a mortality-rate of up to 47 per cent (Bastable, de Jode, and Warren, 1959; Yarwood, 1959). Misdiagnosis is common, the usual diagnosis being peritonitis secondary to a perforated peptic ulcer (Yarwood, 1959).

Acknowledgement.—I should like to thank Professor A. P. M. Forrest, under whose care this patient was admitted, for permission to publish details of this case.

MASSIVE HAEMORRHAGE IN ELEPHANTIASIS NEUROFIBROMA

BY P. MCMASTER

ADDENBROOKE'S HOSPITAL, CAMBRIDGE

SUMMARY

An unusual case of elephantiasis neurofibroma associated with massive haemorrhage occurring in an elderly man is reported.

NEUROFIBROMATOSIS (Von Recklinghausen's disease) is a condition occurring once in 3000 births and is an abnormality of neuro-ectoderm inherited by a dominant gene.

Elephantiasis neurofibroma is a rare feature of the disease and massive life-threatening haemorrhage into it has not previously been reported.

CASE REPORT

Mr. J. C., aged 61 years, was a patient who was known to have Von Recklinghausen's disease. His father had also suffered from this condition and had died of a cerebral tumour.

For a number of years the patient had been noted to have a large pendulous overgrowth of subcutaneous tissue (elephantiasis neurofibroma) situated in the lumbar region. This had caused him no trouble. However, he did have epilepsy, possibly due to cerebral glomal lesions.

The patient was admitted as an emergency in a state of collapse. He was semiconscious, pale, and sweating; his pulse was 140 per minute and blood-pressure 70/40. The central venous pressure was −2 cm. of saline. On his back in the lumbar region was a massive, fluctuant, and tender swelling. It measured approximately 45 cm. in diameter and there were signs of early cutaneous necrosis at its centre (*Fig.* 1).

Immediate resuscitative measures were taken. The patient was transfused with 2 units of plasma and 4 units of blood over the next hour.

Investigations revealed the following: haemoglobin, 6·8 g. per cent; haematocrit, 21; serum sodium, 125 mEq./l.; potassium, 4·5 mEq./l.; bicarbonate, 19 mEq./l.; blood-urea, 64 mg. per cent; serum creatinine, 1·3 mg. per 100 ml. Urine examination was normal. A chest radiograph showed the patchy appearance of bronchopneumonia. In spite of intensive efforts at resuscitation his condition did not improve and the lumbar swelling was clearly increasing in size. An emergency operation was therefore undertaken.

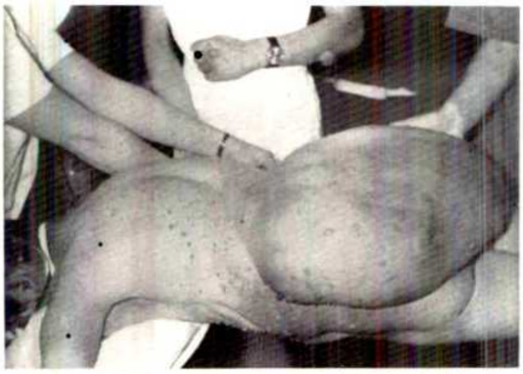

FIG. 1.—Patient prone and anaesthetized, showing the elephantiasis neurofibroma.

With the patient in the prone position the large lumbar swelling was explored through a transverse incision. An enormous superficial cavity was opened and 2·5 litres of blood were evacuated.

At the base of this cavity numerous vessels were found to be bleeding freely and were individually ligated. The neurofibroma was then excised. Redundant skin was also removed and four Redivac drains were left in situ. The transverse incision was closed with interrupted silk. A total of 14 units of blood was transfused during this procedure.

At the end of the operation the patient's condition had improved considerably—blood-pressure 150/90 and central venous pressure +5. His respiration was, however, laboured and he was subsequently bronchoscoped when large quantities of mucopurulent sputum were removed. His pneumonia was treated with ampicillin, 500 mg. 6-hourly for 10 days.

Apart from a small area of skin necrosis in the lower flaps the patient's postoperative recovery was uneventful. He was discharged to convalescence after 3 weeks and remains well 1 year later.

Histological examination confirmed the benign character of the neurofibroma (*Fig.* 2).

DISCUSSION

There have been a number of reports of elephantiasis neurofibroma (Hadil, 1928; Spittal, 1929; Anzinger, 1931; Westcott and Ackerman, 1947) since it was first described (Virchow, 1863).

The typical picture is that of a child presenting with neurofibromatosis (one of whose parents may also have the condition) in whom there appears a slowly developing, large, diffuse overgrowth of subcutaneous tissue and skin of the affected part. The overlying skin may be normal but often it is thickened and pigmented. The lesions are frequently situated around the neck or extremities (Bruns, 1891).

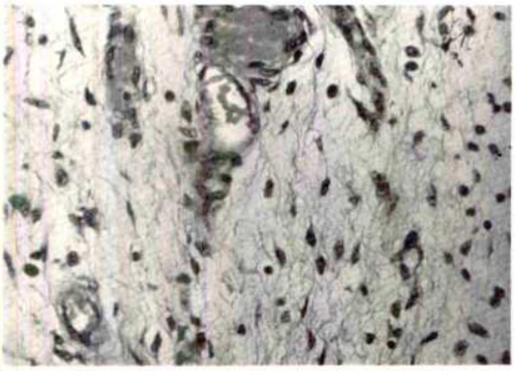

FIG. 2.—Histological appearance, showing oedematous neurofibrous stroma and numerous blood-vessels.

Elephantiasis neurofibromatosis is usually progressive and disfiguring and sarcomatous malignant change occurs in 5–15 per cent of cases (D'Agestino, 1963).

The case described here was associated with an unusual complication requiring vigorous resuscitation and emergency surgery.

Acknowledgements.—I am indebted to Mr. W. G. Everett for his help and encouragement in the preparation of this case and to Mrs. Richardson for her secretarial assistance.

REVIEWS AND NOTICES OF BOOKS

The Laboratory Animal—Principles and Practice. By W. LANE-PETTER, Houghton, Huntingdon, and A. E. G. PEARSON, Welwyn Garden City, Hertfordshire. 9 × 6 in. Pp. 293 + xi. Illustrated. 1971. London: The Academic Press Inc. £4.

IN this era of surgical research, and especially cancer research, this book will be in great demand, for it discusses important subjects such as breeding techniques and animal nutrition. Other subjects which come under consideration are animal-house design, economics, health, administration, and husbandry.

The authors are to be congratulated on having compiled a compendium of present-day knowledge covering every aspect of laboratory-animal science.

This book is bound to be popular for students and research workers in universities, medical, dental, and veterinary schools, and all laboratories using animals.

This is a book of practical importance.

Radiation Effect and Tolerance, Normal Tissue. Basic Concepts in Radiation Pathology. Edited by J. M. VAETH, M.D., San Francisco. 9½ × 6¾ in. Pp. 526 + viii, with 166 illustrations. 1972. Basel: S. Karger. £16·50.

THIS volume is No. 6 in the well-known series 'Frontiers of Radiation Therapy and Oncology'. It is an important volume in this series, for it presents the fundamentals of radiation therapy—radiation pathology. It is well known that tolerance of normal tissues to the effects of ionizing radiation limits the total dose which can be delivered to a tumour and its surrounding tissues over a period of time.

The coverage of this book is vast. The problems of radiation and the microcirculation, radiation tolerance of the skin and the gastro-intestinal tract, and the hepatic effects of radiation are dealt with in a very interesting and practical manner.

Radiation carcinogenesis is discussed at length.

Some valuable tables dealing with radiation effects on various organs are included in this book.

The data presented in this book will help the radiotherapist in his work and should stimulate further basic and clinical research.

An excellent reference volume which should be found in every medical library.

Essentials of Artificial Ventilation of the Lungs. Third edition. By A. R. HUNTER, M.D., F.R.C.S. (Glas.), F.F.A. R.C.S., Manchester. 8½ × 5½ in. Pp. 95, with 33 illustrations. 1972. Edinburgh: Churchill Livingstone. £1·50.

THE success of this useful little monograph is assured. Three editions in ten years is proof of its popularity.

This third edition has been fully revised. It describes lung ventilators in common use and sets out the principles of fluid and electrolyte balance and of patient care. It also includes an entirely new chapter on the diagnosis of death.

An excellent and handy book for students and nurses.

Orthopaedic Surgery in Spasticity. By HAROLD M. FROST, M.D., A.O.A., A.A.O.S., A.B.J.S., Detroit. 9 × 6 in. Pp. 216 + xi. Illustrated. 1972. Springfield: Ill.: Charles C. Thomas. $13.00.

THIS is a stimulating monograph and the author, Dr. Harold Frost, is the ideal man to write such a book because of his mature clinical experience over the past two decades. He has written many books and articles on orthopaedic problems and his background can be seen in the text of this book.

The book is divided into two sections. The first deals with the functional and operational viewpoints. Neurophysiology is portrayed in an original manner. The clinical problems of upper- and lower-extremity spasticity are discussed in an interesting and lively manner. The various corrective surgical procedures are explained in a very practical way. The line drawings throughout the book are original and easy to understand.

Section 2 is mainly clinical. The author describes his experience of many years of working with spastic children at the Crippled Children's Clinic at the Henry Ford Hospital. In this section the author describes some new procedures which in his hands have given excellent results.

Anyone who has to deal with spastics should read this book.

Urologische Operationslehre, Vol. 8. By G. W. MÜLLER, Magdeburg, W. WELRHEIM, Magdeburg, and G. W. HEISE, Magdeburg. 10½ × 7¼ in. Pp. 172. Illustrated. 1971. Leipzig: Georg Thieme. 53 M.

VOLUME 8 of this excellent series on urological surgery deals with plastic operations on the renal pelvis, tuberculosis of the urinary system, and pediatric urology.

Numerous operative methods are demonstrated for keeping vital kidney tissue viable by plastic reduction of the renal pelvis. The theory of aberrant blood-vessels causing hydronephrosis with the consequence of resection of those vessels is obsolete. Indeed, when blood-vessels are compressing the ureter transposition of the ureter is the operation of choice.

In the treatment of tuberculosis nephrectomy is unusual; the aim is to save as much kidney tissue as possible. The treatment by anti-tuberculous antibiotics as mentioned in this book is questionable. Stenosis of calices and the pelvis is more dangerous than the tuberculous infection itself; surgical therapy is started according to this principle, while partial kidney resection may be necessary.

In the section on paediatric urology vesico-ureteral reflux, which is often accompanied by a mega-ureter, gets ample attention; reconstructive operations are promising in such cases.

Operative treatment of ectopia and exstrophia of the bladder is more successful when implantation of the ureters with a roof of bladder-mucosa in the sigmoid colon is performed than in the cosmetically more satisfying plastic reconstruction of Marshall.

An excellent reference book.

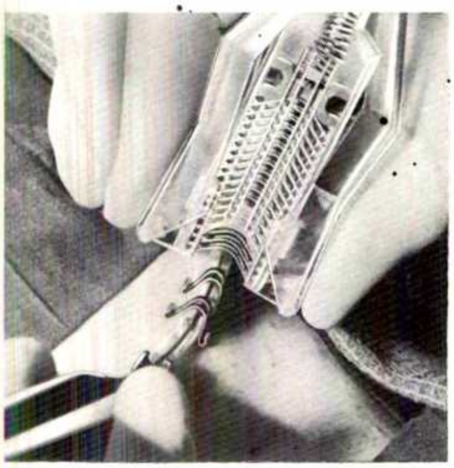
ICI introduces the

AVLOX 18
Trade Mark
SYSTEM

The AVLOX 18 System from ICI provides a new and simple method of wound closure.

Simply hold the wound edges together with forceps and apply clips along the length of the wound.



Obviously this technique offers advantages. It is fast, easy to use and convenient. It reduces the risk of permanent marks because the clips hold and do not generally penetrate the skin.

The AVLOX REMOVER (also illustrated) has been specially designed to minimise discomfort during clip removal.

Both the AVLOX 18 and the AVLOX REMOVER are supplied sterile and ready for use.

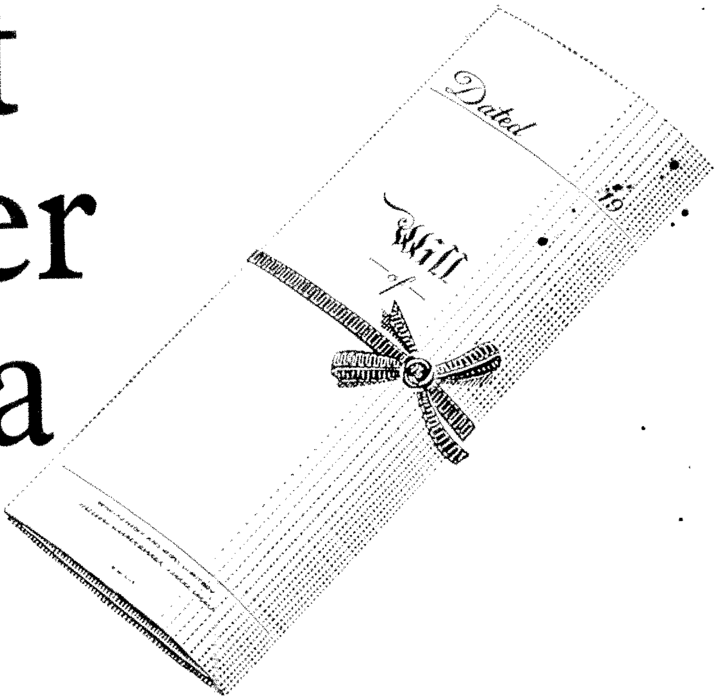
PH802/A

Fight cancer with a will



When testators ask your advice, please remind them of the urgent work of the Imperial Cancer Research Fund. In the Fund's up-to-date laboratories trained minds are using every weapon of modern science to fight all forms of cancer, including leukaemia.

Now one of the world's great research centres, the I.C.R.F. relies entirely on public support. The cancer problem *must* be solved. Please help now.

Patron:
H.M. THE QUEEN
President:
The Honourable Angus Ogilvy

Form of Bequest

I hereby bequeath the sum of.................. pounds free of duty to the Imperial Cancer Research Fund, Lincoln's Inn Fields, London, WC2A 3PX for the purpose of scientific research, and I direct that the receipt of the Honorary Treasurer or Secretary shall be a good discharge for such legacy.

Please write for further information to: The Secretary, I.C.R.F. (Dept 164),
PO Box 123, Lincoln's Inn Fields, London WC2A 3PX

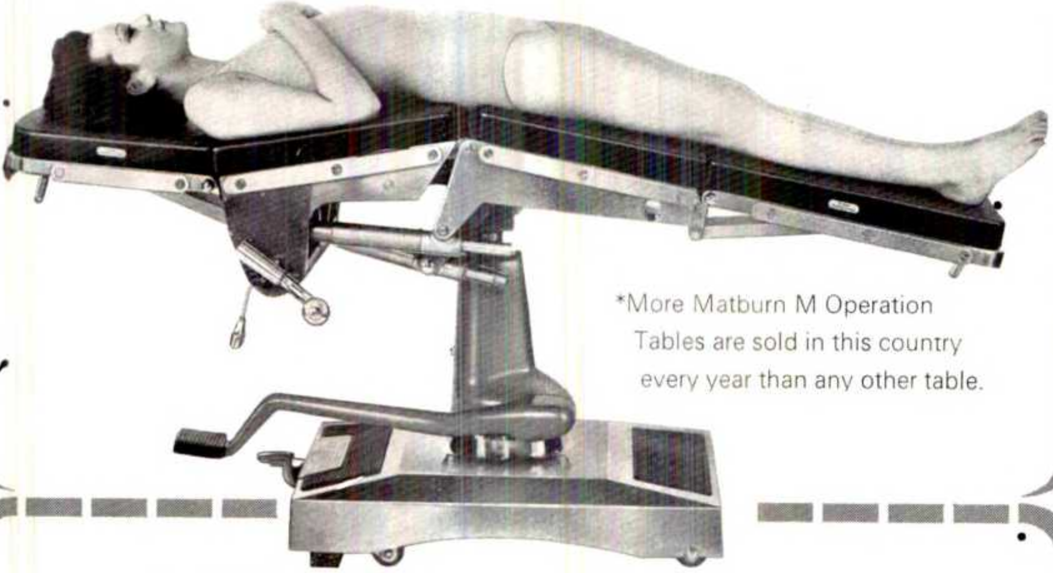
Matburn M

The supreme four section operation table*. . .

This is the supreme four-section operation table: grouped head-end control, the fullest range of positions and a series of over fifty accessories give the M the flexibility to meet the demands of any branch of surgery, and any procedure from routine examination under anaesthesia to advanced neurosurgical operations.

Built to the highest standards of engineering skill and precision, Matburn M combines absolute rigidity with easy mobility when required.



*More Matburn M Operation Tables are sold in this country every year than any other table.

To: **Eschmann Bros. & Walsh Limited**
24 Church Street, Shoreham-by-Sea, Sussex BN4 5EB
I would like to know more about the Matburn M.
Please send a 12 page colour booklet to:

A CLASSIC TEXT

Sabiston:

DAVIS-CHRISTOPHER TEXTBOOK OF SURGERY

(New Tenth Edition)

This new edition of the medical classic provides the surgeon with the latest usable techniques, innovations, and procedures—vital information that can be immediately incorporated into daily practice. For the surgical student, it presents all the information he will need to know—in a single unified source.

Under the editorial direction of Duke University's David C. Sabiston Jr., Davis-Christopher has been revised, rewritten, updated—so thoroughly that it's virtually a new book—retaining only the authority, the clarity, and the breadth of coverage that made its predecessors so widely used.

The main emphasis of the new edition is upon the subtitle, "The Biological Basis of Modern Surgical Practice". Concise descriptions of the pertinent biochemistry, pathology, physiology, and pharmacology of the various disorders, together with their diagnosis and treatment, are given in each chapter. Emphasis has also been given to the quality of the illustrations. Of the some 1,500 illustrations in the text, the majority have been selected from the most authoritative publications on the subject available in the literature.

A number of new chapters in keeping with modern surgical progress have been added. Most are not available in any other text and yet represent a very important part of the surgical present and future. These include: Homeostasis—the Use of Computers and Mathematical Techniques in Surgery—Fever: Etiology, Physiology and Metabolic Effects—Immunobiology of Neoplastic Disease—Respiratory Physiology—Cardiovascular Physiology—Radioisotope Techniques for Diagnosis of Surgical Disorders—Basic and Clinical Transplantation Biology.

Edited by
David C. Sabiston, Jr. MD,
Chairman, Department of Surgery, Duke University School of Medicine, Durham, North Carolina.

Single Volume: 2135 pages. £11·70. Two Volume Set: £14·90 (Vol. I—1002 pages, Vol. II—1133 pages). 1538 illustrations with 6 views in colour. September 1972.

Another surgeon is about to use one of the world's finest surgical blades....
...this happens thousands of times every day!

It happens because the blades are by Swann-Morton, the people who meet the highest requirements in surgical knives.
We need say very little about our superiority. The world's surgeons have proved it for us!

Swann-Morton

SWANN-MORTON LIMITED
PENN WORKS, OWLERTON GREEN

no fear
no infection
no pain

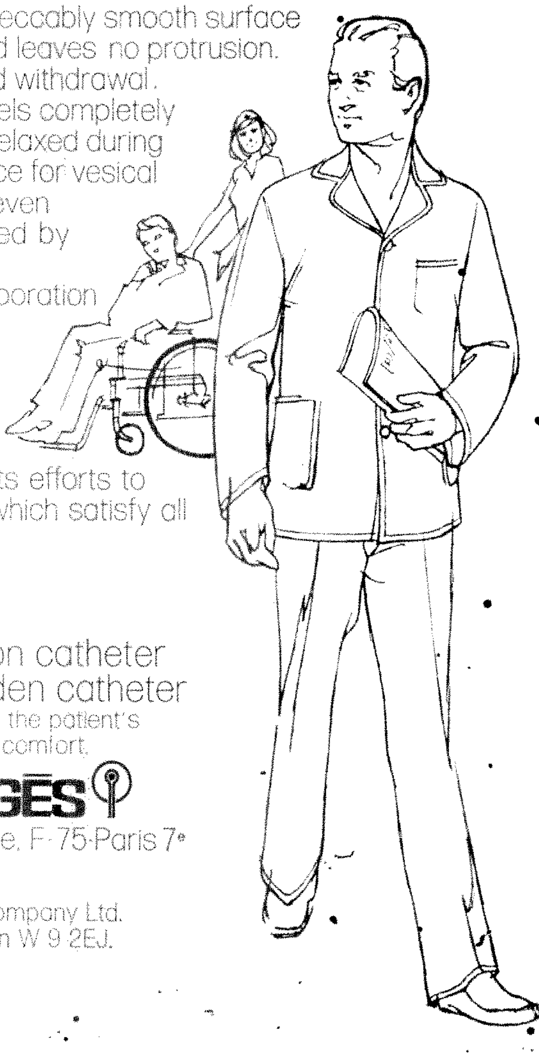
with a Porges golden balloon catheter

No pain : it has an impeccably smooth surface and the balloon when deflated leaves no protrusion. This allows easy insertion and withdrawal.

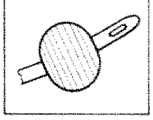
No fear : the patient feels completely reassured. He will be utterly relaxed during catheterization. A large surface for vesical support is obtained through even inflation of the balloon, ensured by reinforcing ribs.

No infection : the incorporation of active bacteriostatic compounds into the latex prevents any urinary tract infection.

Our research department has devoted all its efforts to the production of catheters which satisfy all clinical requirements :



The Porges balloon catheter



the golden catheter
created for the patient's safety and comfort.

John Wright ***RECENTLY PUBLISHED***

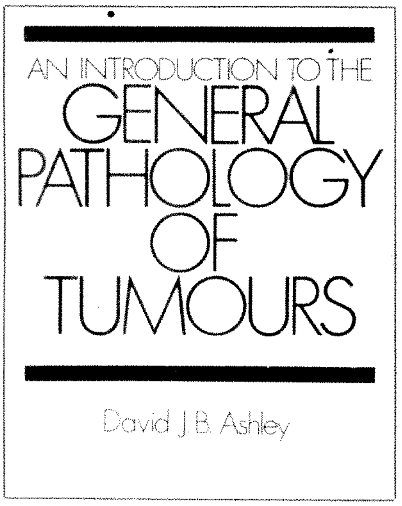
The Principles of Transurethral Resection and Haemostasis

By J. P. Mitchell, T.D., M.S., F.R.C.S., F.R.C.S.E., *Lecturer in Urology, University of Bristol; Consultant Urological Surgeon, United Bristol Hospitals; Consultant Urologist, Southmead General Hospital.*

This book is based on an essay for which the author was awarded the *Jacksonian Prize*, the oldest and most cherished prize of the Royal College of Surgeons of England.

Transurethral resection is essentially a practical subject in surgery, involving the basic principles of surgical technique, with success depending largely on clinical acumen in diagnosis. Not only urologists and trainee urologists but all surgeons can learn much from this book.

276 pages	124 illustrations	**£6·00**



By D. J. B. Ashley, T.D., M.D., F.R.C.P.PATH., *Consultant Pathologist, Morriston Hospital, Swansea.*

This book is offered as a contribution to the application of general medical and scientific principles to the understanding of neoplastic disease in the human. It is directed to the clinician, both undergraduate and postgraduate, who is concerned with the care and management of patients suffering from neoplastic disease and who wants a résumé of current knowledge in this field.

ABO Haemolytic Disease of the Newborn

By E. R. Gold, M.D., *Research Fellow, Department of Child Health, University of Bristol*; and N. R. Butler, M.D., F.R.C.P., D.C.H., *Professor of Child Health, University of Bristol.*

This monograph studies in detail ABO haemolytic disease of the newborn, and will be of interest to blood-group serologists, obstetricians, and paediatricians.

JOHN WRIGHT & SONS LTD., BRISTOL, ENGLAND BS8 1EX

11 NEW TITLES FOR SURGEONS

PLASTICS MATERIALS IN SURGERY (2nd Ed.) *by* **Bernard Bloch,** *Sydney Hospital, Australia, and* **Garth W. Hastings,** *North Staffordshire Polytechnic, Stoke-on-Trent, England.* This completely revised and rewritten Second Edition presents new factual analysis of current applications. A review of every material in current use is covered. A new chapter on the sterilization of these materials is presented with physical and toxicological tests required in the assessments of plastics implant materials. *'72, about 258 pp., about 9 il., 4 tables*

AN ATLAS OF SURGICAL ANATOMY AND TECHNIQUES OF THE TEMPORAL BONE *by* **Ralph J. Caparosa,** *Univ. of Pittsburgh School of Medicine. Foreword by* **Raymond E. Jordan.** *Medical Illustrations by* **Ronald Filer.** Presents several methods of surgery which are meaningful and significant in practice and teaching. The procedures are those which have been performed often enough and for a long enough time so that they represent techniques presently considered to be established and valuable. *'72, 136 pp. (8½ × 11), 108 il. (11 in full color), 1 table, $18.00*

APPLIED SURGICAL ANATOMY *by* **Charles Marks,** *Charity Hospital, New Orleans. Foreword by* **William D. Holden.** Reviews fundamental aspects of anatomy and relates these facts to clinical situations. This text enables one to see more clearly the integration of anatomic facts in clinical and radiologic investigation, and relates the relevance of normal anatomy with its interrelationship to disturbed function. The illustrative materials also include x-ray photographs and examples of pathologic material. *'72, 608 pp., 151 il. (16 in full color), $22.50*

ATLAS OF IMPROVED SURGICAL PROCEDURES FOR COMMON FOOT DISORDERS: Ingrown Toenail and Hammertoe *by* **George C. Wee,** *Veterans Administration Hospital, St. Louis. Foreword by* **Robert H. Witmer.** *Drawings by* **Diane L. Nelson.** Because of the variety of outdated procedures advocated for treatment of these problems, this atlas provides improved procedures which are simple, have a short postoperative morbidity and a low rate of recurrence. Step-by-step procedures explain the operative details of current and best tolerated corrective procedures for these conditions. *'72, 80 pp., 23 il., $6.00*
